	Wear of rails in 12 months. Untreated.	Treated.	No. of cars carried.
Bristol	0·045	0·0157	300,000
Liverpool	0·030	0·0125	200,000

The rails are hardened *in situ*, without otherwise interfering with the track in any way.

When acetylene first made its appearance, its use was confined almost entirely to lighting detached buildings, motor-cars, and cycles.

The advent of electric sets materially reduced the field for acetylene for lighting purposes, but recently there has been a decided revival in this direction, owing to the enormously increased construction of houses of the bungalow type, large numbers of which are situated so far from a centre of supply of coal-gas or electric current that the cost of laying the necessary supply pipes or cables makes the capital outlay too great, in view of the modest requirements per bungalow.

In such cases the very low capital outlay required for an acetylene outfit, its extreme simplicity, and the beautiful light it gives, have made this form of lighting extremely popular.

The use of the oxy-acetylene blowpipe has continued to increase during the past year; indeed these and other applications have so greatly extended the use of acetylene that whereas the consumption of carbide before the war amounted to about 28,000 tons, it rose in 1925 to 40,000 tons per annum. There was a set-back, owing to the difficulties in the coal industry, but at the time of writing a consumption of approximately 40,000 tons a year has again been reached.

The use of acetylene in other directions than as a combustible again made great strides in the past year. One of the most interesting new derivatives is the 'Meta' block, which has been placed on the market by a Swiss firm. This block resembles in appearance solidified methylated spirit, but in its properties it is greatly superior, inasmuch as the block does not liquefy when burning, nor evaporate even if exposed to the air for many months.

Acetylene as obtained from ordinary generators contains a certain amount of impurities. The use of the acetylene blowpipe for welding high-class steels has shown more and more clearly the necessity for removing these impurities from the gas, a purification which can easily be effected by the use of such purifying materials as catalysol, heratol, etc.

One pound of commercial calcium carbide, when acted upon by water, yields on an average about 4·5 cub. ft. of the gas.

Before the war the price of carbide was about £12 10*s*. per ton, packages included. The price is now about £16 to £18 in the United Kingdom, while it is still higher in many of the countries producing it.

Dissolved Acetylene.

By an Order in Council issued in 1897 the compression of free acetylene was made illegal, but further orders were issued in 1901 and 1912 exempting the process now known as 'dissolved acetylene.' This is acetylene thoroughly purified and washed, and compressed into steel cylinders previously filled with a porous mass and having a fixed quantity of acetone added. Acetone is a liquid hydrocarbon, having the property of absorbing 25 times its own volume of acetylene at one atmosphere and 15° C.

For each additional atmosphere of pressure, the same proportion of gas is absorbed, but an allowance has, of course, to be made not only for the volume occupied by the porous filling of the cylinder, but, in addition, in order to allow for expansion, so that it is customary to charge these cylinders with only 43 per cent. of acetone.

A cylinder will therefore in actual practice contain about 100 times its own volume at 10 atmospheres pressure and about 150 times at 15 atmospheres pressure.

In order to show the enormous capacity for storing light obtained in this manner, it may be mentioned that the standard oil-gas cylinder in use on railways has a capacity of 14 cub. ft. at atmospheric pressure. As the oil-gas is usually compressed to 12 atmospheres, this gives a gas volume of 168 cub. ft., which, if filled with oil-gas, will supply eight burners using 2 ft. per hour and burning eight hours per day, for about a day and a half. If this cylinder were filled with porous material and acetone in the manner described above, and charged with acetylene at 15 atmospheres, its capacity would be 2,100 cub. ft., or sufficient to supply eight acetylene burners of 1 cub. ft. each (giving a most brilliant light), for about thirty-three days (basing on eight hours' lighting per day), before the cylinders would require to be re-charged.

The possibility of obtaining acetylene in compressed form opens up a very wide field for the expansion of its utility.

The tests carried out by the Home Office Authorities before issuing the exemption order of 1901 were exhaustive, and furnished satisfactory proof of the safety attending the process of manufacture and the use of the cylinders.

Storage of Dissolved Acetylene.

Acetylene dissolved in acetone and stored, under a pressure not exceeding 225 lbs. per sq. in., in a vessel filled as completely as possible with some porous substance is not deemed an explosive, and can therefore be manufactured, stored, and used without risk of infringing the Explosives Act.

(See also 1919 Order in Council, 'Dissolved Acetylene.')

Porous Material.—Various types of filling are in use and appear to give satisfaction. The porosity of the material should not exceed 80 per cent. The material should completely fill the receptacle, and should contain no pockets or cavities.

The Solvent.—Acetone is the most suitable commercial solvent, but substitutes for acetone could be permitted. The solvent should not completely fill the porosity of the material under any rise of temperature likely to be met with in practice.

Pressure Allowed.—The pressure can be 225 lbs., provided the cylinders used are of the solid drawn type, the pressure to be measured at 60° F.

The Cylinders.—The cylinders should be made of mild steel containing not more than 0·25 per cent. of carbon and not more than 0·05 per cent. each of phosphorus and sulphur. The test pressure should be four times the working pressure, and should be maintained for not less than fifteen minutes. All cylinders should be annealed, but the use of fusible plugs, at present compulsory on acetylene cylinders, should be discontinued, as they are apt to become loose and, further, in the event of fire occurring, may actually lead to the fire being augmented.

It is not considered necessary to impose any conditions as regards the retesting of acetylene cylinders beyond requiring them to be thoroughly examined visually at intervals. The form of retesting to which oxygen and other cylinders are subjected cannot readily be applied to acetylene cylinders with their content of porous material and solvent.

Acetylene Lighting.

For the illumination of buildings, towns, and large areas by acetylene, generators of some suitable type are in general use.

Dissolved acetylene is used successfully from an economical and efficient point of view for many purposes where a constant supply of acetylene is required, and is particularly adaptable where space available for the apparatus is strictly limited.

In the matter of motor vehicle lighting it has been very extensively adopted. A cylinder containing acetylene absorbed in acetone under pressure and of convenient size is attached to the footboard or other suitable position on the car. Such a cylinder contains a sufficient supply of acetylene to meet the requirements for the lighting of the necessary lamps. The time for which the supply is available is variable according to the rate of consumption; the pressure of gas in the cylinder is reduced by an automatic governor or regulating valve, and the supply in the service pipes is maintained at a constant pressure to the lamps.

The standard automobile cylinders contain 20 cub. ft. and 40 cub. ft. of dissolved acetylene, and by the exchange system originated by the manufacturers it is possible for users to obtain refils at practically all important garages throughout the country.

Larger vehicles, such as motor omnibuses, mail vans, motor lorries, etc., may be equipped with outfits of larger capacity to meet the requirements of any particular case.

Another recent departure is the manufacture and circulation of cylinders containing dissolved acetylene of such capacity to meet the demands of motor cyclists. These cylinders are standardised and contain 5 and 10 cub. ft. of acetylene, and, as with the standard cylinders for automobile work, they may be exchanged throughout the country.

For buoy and coast lighting dissolved acetylene has many advantages. The purity of the gas in this form, which is assured before compressing, gives the light increased brilliance and greater penetrating power, hence a shorter light period can be employed than with any other illuminant. Various special apparatus are in use, in which flashes of long or short duration are obtained by automatic means, the light being extinguished between the flashes instead of obscured (a small bypass burner remaining alight), thus economising gas. In some cases a flash of as short duration as one-tenth of a second is obtained, with perfect accuracy and flame. By means of this economical consumption and the great storage capacity of a comparatively small cylinder, a gas supply for periods as long as 12 months can be easily carried on a buoy, no attention being required until the gas is exhausted, when the cylinder is disconnected and replaced by a full one. The cylinders may be arranged in the form of a battery where larger consumption is involved.

Owing to the smallness of space required for acetylene in this form it is particularly adaptable for lighting railway coaches, yachts, and small craft. The effect of atmospheric temperature on the gas in this form is almost negligible, and other advantages are obtained by reason of the purity of gas and the elimination of handling carbide, water, waste and residue, and by the fact that the gas in this form can be stored indefinitely without deterioration.

The applications of this form of acetylene are ever increasing, and it has been recently applied with success to cinematographs, searchlight, signalling and projection work, where a small and compact plant consistent with efficiency is required.

The most recent application for illuminating purposes is that of its adoption for portable hand-lamps for mining and other similar purposes.

Lately acetylene buoys have commenced to displace other forms of coast-lighting to a very considerable extent. Such buoys take a very large charge of calcium carbide, usually one to two tons. They are entirely automatic, require practically no attention, and as they run for six to twelve months before requiring recharging, they form an exceedingly economical means of coast and harbour-lighting. Another great advantage is the fact that the light can be recognised at a much greater distance than that of the oil, or oil-gas, buoys previously used.

PETROL AIR GAS.

(*Contributed by E. Scott-Snell, A.M.S.E.*)

Petrol gas is made by impregnating air with the vapour of petroleum spirit, this mixture being sent through pipes in the usual way for combustion with incandescent mantles. The essential features of an apparatus for producing this gas are an air compressor, a carburettor—in which the air and petrol are brought into contact—and a gas-holder from which the pipe service is fed. In automatic apparatus, *i.e.* machines in which gas is made according to the demand, the holder is also used as a governor for controlling the supply of air and petrol to the carburettor. The relative proportions of air to petrol are very important: in fact, upon the relation of these ingredients, and the constancy of this relation under varying load and climatic conditions, the success or failure of any apparatus must depend. As a mantle is used for light-giving, a flame is required at the burner which shall give the highest possible temperature, *i.e.* the amount of air mixed with the petrol vapour must be such as to completely combust it. With the more volatile spirit, mainly hexane (C_6H_{14}), used for making this gas, complete combustion is assured when approximately two volumes of vapour are mixed with 98 volumes of air. This is calculated from the typical equation $2C_6H_{14} + 19O_2 = 12CO_2 + 14H_2O$ representing the combustion of the chief constituent of light spirit. At present, opinion seems to be divided as to the advisability of sending such a mixture—which from its composition is obviously an explosive one in a confined space

such as a gas-holder—through the system. It is found, however, that when the percentage of vapour in the mixture exceeds 4½ per cent., *e.g.*, a 5 per cent. or 6 per cent. mixture, the gas is incombustible without the addition of further air, and in the better class machines advantage is taken of this fact to make a slightly richer gas than 4½ per cent., diluting it with the extra air required for complete combustion by the aid of Bunsen burners.

The air-compressing apparatus of a petrol gas machine may be actuated by any motive power, but as the work of forcing the gas through the pipes is comparatively light, nothing more powerful than a hot-air motor or wound-up weights is usually required. In a good apparatus, the relative amounts of air and petrol are mechanically measured before passing to the carburettor, so that constancy of mixture is obtained under all conditions of temperature within wide limits. When other means are adopted, such as leading the air across a bath of petrol, selective evaporation takes place, producing erratic results, the make of gas varying with every change of temperature. In fact, attempts to make apparatus of this sort automatic almost inevitably end in failure.

Petrol gas is probably one of the safest lighting mediums known, by reason of the small compass over which mixtures of petrol vapour and air are explosive (1½ per cent. to 4½ per cent., c.f. acetylene 3·3 per cent. to 52·3 per cent., coal-gas 7·9 per cent. to 19·1 per cent.) and the fact that over 90 per cent. of the escaping gas from any leak is air. It is also non-asphyxiating.

The gas varies in calorific value according to the proportions of the mixture and the spirit used, but a 6 per cent. mixture from 0·680 sp. gr. petrol has a gross calorific value of nearly 300 B.Th.U. per cubic foot. Although this is a comparatively low figure, cooking and heating can be efficiently performed with suitably proportioned burners.

One gallon of light spirit gives 5,000 candle-power hours (Lewes). With petrol at 1*s*. a gallon this is equivalent to 2·4*d*. per 1,000 candle-power hours. The Government tax of 3*d*. per gallon is remitted when petrol is used for purposes other than propelling road vehicles.

Petrol gas can be stored almost indefinitely over water, but since a small 'Bijou' mantle requires anything from 4 to 12 cub. ft. per hour (according to whether a 6 per cent. or 2 per cent. mixture is used) the storage of any reasonable quantity of the gas entails the use of very large holders. Hence the advantage of the weight-driven type of automatic generator.

Attempts are being made to effect economy by using the less volatile petrols of 0·720 to 0·760 sp. gr. for lighting purposes, such as are in general use for motor cars. The physical characteristics of these spirits, however, are such that they do not lend themselves readily to cold carburation, for either considerable quantities will pass through the carburettor unvaporised, or if heat is used to evaporate them, heavy condensation is unavoidable in the pipe service, which must necessarily be very carefully laid to provide for it.

An explosive (or 'weak') mixture in the pipes and holder is unavoidable if heavy spirits are used, since they are not sufficiently volatile to allow of the use of a 'rich' mixture. See also Scott-Snell on 'Petrol Air Gas,' Soc. of Eng. Journal and Trans., March 1911; Illuminating Engineers' Soc. Journal and Trans. February 1913.

Heating Value and Candle-Power of Petrol-Air Gas.

According to the Snercold Engineering Co., as the result of tests of a variety of different brands and grades of petrol, the fair average heating value of a gallon of petrol is 143,500 B.Th.U., and the maximum candle-power hours that can be obtained under the best conditions is 6,025. The following table shows different mixtures in percentages of petrol vapour used; for calculation purposes the heating value has been taken as 143,000 B.Th.U., and the candle-power hours as 6,000 per gallon.

TABLE SHOWING VARIOUS MIXTURES OF PETROL-AIR GAS.

Mixture Percentage of Petrol Vapour.	Gallons per 1,000 Cubic Feet of Gas.	Heating Value B.Th.U. per Cubic Foot.	Cubic Feet of Gas to the Gallon.	Candle-power Hours per Cubic Foot.
6	2·184	312	458·3	13·104
5½	2·0	286	500	12·0
5	1·82	260	555	10·92
4½	1·638	234	612	9·828
4	1·4638	208	687·5	8·7828
3½	1·274	182	785·7	7·644
3	1·092	158	916·6	6·552
2½	0·91	130	1100	5·46
2	0·728	104	1375	4·368
1½	0·546	78	1833·2	3·276

The heating value of coal-gas varies from 420 to 550 B.Th.U. per cubic foot according to the source of supply.

HEAT TREATMENT OF GAS CYLINDERS.

(*Second Report.**)

In view of experiments made by the Gas Cylinders Research Committee the Committee agree that the periodical re-heat treatment of carbon steel gas cylinders which have not been obviously damaged, serves no useful purpose, and they recommend that the practice be discontinued.

AMOUNT OF HEAT REQUIRED.

Heat Losses.

When any room or building is maintained at a higher temperature than the outside air there is a loss of heat from the structure through walls, windows, etc., and also a loss due to air change. Modern practice demands that these losses shall be estimated as accurately as possible. A few of the more usual factors for materials in common use are tabulated below, the figures being the loss in B.Th.U.'s per hour per sq. ft. per deg. F. difference between inside and outside temperature.

Material.	Loss in B.Th.U.'s.
Walls.	
Brick wall 4½ ins. thick with plaster inside	0·57
Brick wall 9 ins. thick with plaster inside	0·43
Brick wall 13½ ins. thick with plaster inside	0·35
Brick wall 18 ins. thick with plaster inside	0·29
Brick cavity wall 11 ins. thick, 2 ins. air space	0·34
Brick cavity wall 15½ ins. thick, 2 ins. air space	0·29
Concrete wall 4 ins. thick	0·64
Concrete wall 8 ins. thick	0·47
Brick wall 9 ins. thick with 4 ins. stone facing	0·40
Windows.	
Single window	1·0
Double window	0·5
Floors.	
6 ins. concrete on earth	0·20
Concrete on earth with wood blocks	0·15
1 in. wood floor with air space under	0·40
Ceilings and Roofs.	
Plaster ceiling with air space above (roof boarded and felted with tiles or slates)	0·30
Concrete 6 ins. thick, finished asphalt	0·57

It is usual to allow for the air contents of a room (natural ventilation) to be changed from 1 to 3 times per hour. A usual figure for office blocks, etc., would be 1½ to 2, while for hospitals, etc., at least 3 changes should be allowed.

The heat to be allowed for air change can be ascertained by multiplying the total quantity of air to be heated per hour by 0·019 for each deg. F. of the required rise.

'The Computation of Heat Requirements for Buildings,' published by the Institution of Heating and Ventilating Engineers, gives data for many types of building materials together with recommended allowances for air change and suitable room temperatures for many classes of buildings.

The total heat requirements for heating a room or building are the sum of the heat required to warm the incoming air plus the heat required to replace that lost through walls, windows, floors and ceilings, found by multiplying the various surface areas by the coefficients given in the above table and by the difference between the internal and external air temperatures.

It is usual practice to make allowances on the heat losses estimated by means of the above co-efficients according to the exposure of the building or room. This varies according to the aspect and may increase the total emission through the surfaces by as much as 15 per cent. for brick walls, 30 per cent. for glass, and 20 per cent. for flat roofs. Similarly in sheltered positions the emission is reduced. For buildings in towns and cities and in positions not particularly sheltered or exposed, the co-efficients given will be found suitable. Again, however, allowance in the amount of heating surface and the output of the boiler should be made according to the way the heating installation will be operated. In the case of buildings with very intermittent use such as churches or public halls which are only occupied one or two days a week, the heating not being maintained when the building is unoccupied, it is usual to increase the heating surface by approximately 60 per cent., the boiler power being increased by 100 per cent. For office buildings where the boiler is banked at night, it is desirable to increase the heating surface by approximately 10 per cent. and the boiler power by approximately 50 per cent.

The effect of the wall finishings on the heating-up period of a room, that is, the time taken to reach comfort conditions after a period of non-occupancy, needs more consideration than it usually receives. Experiments carried out by Mr. A. F. Dufton* demonstrated that particular rooms were warmer after half an hour's heating when the walls were panelled with wood than they were after an hour and a quarter's heating when the walls were only plastered. It follows that in cases of intermittent heating, as for example an office block where the period of occupation is 8 or 9 hours a day, it is an advantage if the walls are finished with some material of small thermal capacity, of which wood is a good example.

Heating Surface.

The most common form of heating surface is the ordinary cast iron radiator. Though this name is used, it is, of course, well known that the heat emitted by a radiator is both by radiation and convection; the usual proportion for this being 30 per cent. radiation and 70 per cent. convection. The average figures for total emission from radiators vary between 150–185 B.Th.U.'s per hour per sq. ft. of surface with a difference of temperature between the room and the mean radiator flow and return of 100° F. The following list gives the approximate emission for the different types of cast iron radiators available at the present time, small variations occurring between the different makes:

Two column .	185	B.Th.U.'s per hour per sq. ft. of heating surface for 100° F. diff.
Four column .	170	,, ,, ,, ,, ,, ,, ,, ,, ,,
Six column . .	160	,, ,, ,, ,, ,, ,, ,, ,, ,,
Wall . . .	171	,, ,, ,, ,, ,, ,, ,, ,, ,,
Hospital (Narrow)	185	,, ,, ,, ,, ,, ,, ,, ,, ,,
Hospital (Wide) .	151	,, ,, ,, ,, ,, ,, ,, ,, ,,

If radiators are placed in any kind of enclosure, or fixed behind grilles, an allowance of from 5 to 30 per cent. extra surface should be made to counteract the loss of efficiency of the surface —very often the greater part of the radiant emission is lost and the circulation of air over the hot surface much impeded.

The heat emission from radiators depends upon the difference between the mean temperature of the water or steam in the radiator and the surrounding air temperature. To find the approximate heat emission from radiators for various water and air temperatures, the above emissions may be multiplied by the factors given in the following table.

TABLE OF FACTORS FOR MULTIPLYING STANDARD RADIATOR AND PIPE EMISSIONS FOR VARIOUS AIR AND RADIATOR TEMPERATURES.

Mean Radiator Temperature. °F.	Inside Air Temperature. °F. 45	50	55	60	65	70	75
140	0·93	0·87	0·81	0·75	0·69	0·63	0·57
150	1·07	1·00	0·93	0·87	0·81	0·75	0·69
160	1·21	1·13	1·07	1·00	0·93	0·87	0·81
170	1·35	1·27	1·21	1·13	1·07	1·00	0·93
180	1·48	1·41	1·35	1·27	1·21	1·13	1·07
190	1·63	1·56	1·48	1·41	1·35	1·27	1·21

* *Proc. Inst. Heat. and Vent. Eng.*, vol. xxx, p. 132.

The amount of heat to be provided in each room by the radiators may be found by subtracting the heat emission of the circulating pipes from the total heat losses. The heat emission in B.Th.U.'s per hour per lineal foot of horizontal pipe, freely exposed, with a temperature difference of 100° F. between the pipe and air temperature is given in the following table :—

Nominal Bore of Pipe. Ins.	Emission B.Th.U.'s per Lineal Ft. at 100° F. Temperature Difference.
½	56
¾	68
1	82
1¼	101
1½	113
2	138
2½	163
3	191
4	243
5	291
6	337

To obtain the approximate emission from pipes for various pipe and air temperatures the emissions given above may be multiplied by the factors given in the previous table. The emissions from vertical pipes freely exposed are approximately 95 per cent. of the above figures and if pipes are near walls or ceilings the emission is about 80 per cent. of a freely exposed pipe. For horizontal pipe coils where the pipes are placed one above the other the emission for each pipe will be reduced by 5 per cent. for two pipes, 15 per cent. for four pipes and 25 per cent. for six pipes.

The use of low temperature radiation is becoming much more popular in modern heating installations. The heating surface employed when this type of system is installed consists in the main of two alternatives : (*a*) superimposed panels, and (*b*) embedded panels. Superimposed panels may consist of cast iron sections nippled together, or may consist of steel plates provided with a system of waterways on the back. In the case of embedded panels, pipe coils consisting of ½ in. or ¾ in. steel or copper tube at 6-in. centres are embedded in the face of the structure behind the plaster. These panels may be placed anywhere in the room, but the most convenient position is in the ceiling. The emission in the case of superimposed panels fixed to the ceiling is approximately 80 per cent. by radiation and 20 per cent. by convection, while in the case of the embedded panels the radiation component may be even higher.

With embedded panels these are usually laid on the shuttering during construction of the building, the concrete being poured over the pipes and fixing them in position. To ensure a proper key for the plaster, slip tiles should be provided between the pipe coils or some other provision made. Special precautions must also be taken to ensure that the plaster employed is a first-class specification, the final coat being reinforced by means of a layer of scrim worked in with a trowel over the whole of the surface below the panel and extending 6 in. to 12 in. on each side of the embedded coil. Firms who specialise in this form of heating will provide satisfactory specifications for the plaster work. It is also usual to limit the temperature of the water in the system to a maximum of 130° F. to reduce the risk of cracking due to the expansion of the pipes. When panels are embedded in the ceiling under a flat roof, insulation consisting of not less than 2 in. of cork should be provided over the whole of the roof.

When designing a heating installation for a building in which air change is expected to be relatively large, as for instance open air schools, sanatoria, hospitals, etc., it is desirable to arrange that the heat shall be provided mainly in the form of radiant heat. To meet this condition, particularly for Open Air schools, floor heating has been developed in which the surface temperature of the floor is maintained at not more than 70° F.

It is fairly common to find radiators finished with aluminium paint, or decorated with one of the bronze powder finishes, the result being that the radiation is appreciably diminished. This is shown by the following table which is the result of experiments carried out by the Department of Scientific and Industrial Research at the Watford Research Station, and set out in their Food Investigation Board Special Report, No. 9 (revised edition, 1931):

'Taking emissivity of dead black as unity, and expressing the values for other materials as fractions of this, we have—

'Dead Black	1·0
Black paint	1·0
Black enamel	1·0
Dark Green paint	1·0
White paint or enamel	1·0
Aluminium paint (one coat)	0·7
Aluminium paint (two coats)	0·5 to 0·7
Aluminium paint (rubbed with fine sandpaper)	0·8
Dull copper surface	0·15.'

The above figures are, of course, only applicable to the radiant heat given out by a radiator, the effect of different finishes on the heat given out by convection being practically nil.

The actual amount by which the total emission (by radiation and convection) is affected will in any particular case depend on the type of surface, and be much more serious where a large part of the emission is in the form of radiation.

In the case of radiators the use of aluminium or bronze paint may reduce the total emission by up to approximately 12 per cent., and in the case of superimposed panels on the wall this reduction may be as much as 25 per cent., and in the case of superimposed panels on the ceiling as much as 36 per cent.

While the amount of heating surface required should always be calculated from a careful estimate of the heat losses from the building, the following figures giving the amount of heating surface in the form of hot-water radiators and exposed pipes required for various types of building per 1,000 cub. ft. contents may be taken as a rough guide :—

Type of Building.	Surface required. Sq. ft.
Hospitals	20–35
Offices	15–20
Public buildings	12–15
Churches	12–15
Theatres	5–10
Houses	10–15
Shops	7–10

For horticultural work the following figures may be taken as representative :

Type of House.	Approximate Surface in ft. super per 1,000 cub. ft.
Houses requiring to be kept at a temperature above 35° F. in order to prevent frost entering	16
Peach and similar houses	27
Greenhouses	40
Tomatoes, vines, etc.	60
Forcing pits	130

Effective Temperature and Equivalent Temperature.

During the last few years, the effect of radiant heat on comfort conditions has received much consideration. It is generally accepted that the readings of an ordinary thermometer do not always give a true indication of the actual feeling of comfort in a room. With a proportion of radiant heat, comfortable conditions seem to be obtainable with a lower air temperature than would be necessary if no radiant heat were available.

The American term 'effective temperature' has been brought into use. This is derived from measurements of (1) dry bulb temperature ; (2) wet bulb temperature ; and (3) air velocity. The figures corresponding to different values of the above variables are set out on psychrometric charts from which the effective temperature for any set of conditions can be ascertained. These charts, while no doubt being useful in America for determining the indoor comfort conditions in summer, do not take into account the effects of radiation.

The Royal Naval Personnel Research Committee of the Medical Research Council has recently adopted a scale of measurements called 'Corrected Effective Temperatures.' With this scale a correction is made to the Effective Temperature Chart by using the readings of the Globe thermometer instead of the ordinary thermometer. The globe thermometer which was devised by Dr. H. M. Vernon is a 6-in. diameter copper globe painted matt black and containing an ordinary thermometer with its bulb at the centre of the sphere. The temperature of the instrument is mainly influenced by radiant heat and air temperature and to some degree by air movement. The publication by H.M. Stationery Office entitled 'Environmental Warmth and its Measurement,' by Dr. T. Bedford, explains the use of The Effective Temperature Scale under normal conditions, and conditions of high temperatures and humidities.

Another measurement of comfort called equivalent temperature is commonly used in England. (The term for this was originally the same as the American, but has been altered to avoid confusion.) The equivalent temperature of an environment is defined as 'that temperature of a uniform enclosure in which, in still air, a black body of sufficient size would lose heat at the same rate as in the environment, the surface temperature of the body being one-third of the way between the temperature of the enclosure and 100° F.'

The Building Research Station at Watford has developed an instrument called the Eupatheoscope, for recording equivalent temperature. This instrument consists of a black-painted, hollow copper cylinder, whose surface is maintained at a temperature in accordance with the above definition. The heat input required to maintain the surface of the instrument at this temperature in any room gives a measure of the equivalent temperature of the room.

Whilst the Eupatheoscope admirably serves the purpose for which it was designed, namely, the examination of ordinary conditions of artificial heating, it takes no account of the effects of such factors as humidity at high temperature, etc.

Contract Temperatures.

Many attempts have been made to develop formulæ to predict the internal building temperature when the heating installation is run at its designed temperature but the external temperature is different from the design temperature. These should be used with extreme caution since none take into account the effect of rising or falling external temperature or the thermal capacity of the building. Further, the effect of air change being different from that estimated has a very considerable effect on the final result.

Boiler Power.

It is good practice to allow for a listed boiler power from 25 per cent. to 33⅓ per cent. more than actually indicated by the heat emission from the heating system. This provides a margin for quick heating up from cold when necessary, and also tends to fuel economy, a boiler worked habitually at or above its rated capacity being generally much less efficient than when it has a good margin. In cases where the heating is intermittent the margin should be greater as previously indicated.

The boiler heating surface, as listed by the makers of boilers, is of little use in determining the output unless the proportion of primary and secondary surface is also known. In general it is better to rely on the makers listed output in B.Th.U./hr. Boilers of ample size for their duty give higher efficiencies, due to the lower temperature of the flue gases passing to the chimney.

Efficiency of Heating Boilers.

As regards efficiency, a boiler of moderate size may well give 70 per cent. or even more under test conditions at makers' works, but the overall efficiency under actual working conditions would hardly equal this figure, except for very large plants, a more usual figure being 50 per cent. or 55 per cent., and many boilers, with unskilled attention and long firing intervals, undoubtedly do not maintain 30 per cent. efficiency.

Fuels and their Relative Costs.

The above remarks regarding efficiency refer generally to solid fuel hand fired, the fuel most commonly used being coke. Anthracite is also a most suitable fuel to use in central heating boilers, although it is not often that this can be obtained at a price economical enough to compare favourably with coke. In recent years small graded bituminous coal has been used to a considerable extent for firing boilers by means of automatic stokers. These consist essentially of a hopper from which the fuel is fed by means of a worm into a retort built into the base of the boiler, air provided by a fan being introduced through slots in the sides of the retort. These stokers are thermostatically controlled, the rate of burning being adjustable to suit the requirements so that steady boiler temperatures can be maintained within fairly close limits.

For central heating and hot water supply installations the use of oil as a fuel has many advantages in regard to cleanliness, storage space and labour for operating and many large and small solid fuel plants have been converted to burn fuel oil. Small installations usually comprise semi- or fully-automatic plant, with thermostatic control, burning gas oil or fuel oil (200 seconds Redwood No. 1 at 100° F.). For large plants where maintenance labour is available the cheaper heavy oil having a viscosity of 960 seconds is generally burned with semi- or non-automatic equipment.

Town gas is also a very useful fuel, which lends itself to automatic control, and while largely used for small and medium sized installations of hot water supply, and in a lesser degree for central heating, it is generally found that for large central heating installations its cost is prohibitive, except when it can be obtained at, say, 6*d*. per therm (100,000 B.Th.U.'s), equivalent to 2*s*. 6*d*. per 1,000 cub. ft., when the matter requires careful consideration, as it must be remembered that with gas, as with oil firing, a certain proportion of the labour costs can be saved.

Electricity, owing to its higher prime cost, when compared with most other fuels, is chiefly of use in small or medium installations where running costs are not the first consideration. There are two general methods of utilizing this source of heat: (1) by thermal storage, and (2) by installing direct heaters—either tubular heaters or low temperature panels, or radiants—at the points at which the heat is actually required. When a thermal storage system is employed, current can usually be obtained at special rates during the night time, or other off-peak periods, and used to raise the temperature of water contained in large storage cylinders. During the period the heat is required this water is circulated as in an ordinary heating system, the required flow temperature being maintained by special automatic mixing valves. The price of current must, however, be exceedingly low, say in the neighbourhood of 0·5*d*. per unit, before this method can be considered on a cost basis, even when reduced labour charges, etc., are taken into consideration.

Electric heaters, either as electric fires, tubular heaters, or high or low temperature panels, are particularly useful in cases where the heat is required for short, intermittent periods only, as the heat is available almost as soon as the current is switched on, and can be turned off when no longer required.

In estimating the relative cost of various fuels, other factors besides the price paid have to be borne in mind, the chief of which are the calorific value of the fuel, the efficiency of the boiler plant and the labour costs involved.

A third method of using electricity for space heating has been developed in recent years. This system which uses a refrigerator for heating is known as the Heat Pump and may be installed where there is a source of low grade waste heat such as river water; provision being incorporated in the design to utilise the heat given up by the condenser and to discard the substance from which heat is extracted in the evaporator. When electricity is used to drive the compressor of the refrigerator the heat value of the energy used is only a fraction of that required to raise the temperature of the refrigerant, the rest of the heat being obtained from the substance surrounding the evaporator coils. In practice the heat provided by the condenser is some three or four times the heat value of the electricity used depending upon the relative temperatures and the efficiency of the compressor.

Insufficient information is available to prove that the installation of a Heat Pump is an economical proposition in all cases, but where refrigerating apparatus is installed for other purposes such as air conditioning it may be used economically for heating in winter providing a supply of waste heat is available.

Table I gives a list of the usual fuels, their probable calorific value, and the B.Th.U.'s obtainable from each for 1*d*. in round figures at the prices shown, which it will be appreciated may vary very widely at the present time and are based on convenient round figures so that an estimate of the probable cost of fuel can be made readily by adjusting the figures in accordance with the prices ruling at the time the estimate is made.

TABLE I.

Fuel.	Basic Price.	Calorific Value.	Gross B.Th.U.'s per 1*d*. at 100 Per Cent. Efficiency.	Approx. Cost per Therm. (100,000 B.Th.U.'s.)
Coke . . .	80/– per ton	11,500 B.Th.U.'s per lb.	26,800	3·72
Coal . . .	80/– „ „	11,500 „ „ „	26,800	3·72
Anthracite . .	100/– „ „	14,000 „ „ „	26,160	3·83
Fuel Oil . . .	£10 „ „	19,000 „ „ „	17,750	5·64
Town's gas . .	10*d*. per therm	—	10,000	10·0
Electricity (off-peak)	0·5*d*. per unit	3,415 B.Th.U.'s per unit	6,825	14·66

Table II gives the usual boiler efficiencies for the different classes of fuel and makes allowance for the probable labour costs, the final column gives the cost per 100,000 B.Th.U.'s taking these two factors into consideration. The remarks given above regarding fuel costs ruling at the time the estimates are made, apply also to this table.

TABLE II.

Fuel	Size of Installation.	Cost per Therm from Table I (see note above).	Running Boiler Efficiency. (Per cent.)	Equivalent Cost per Therm.	Cost per Therm including Labour. (Approx.)
Coke	Small	3·72*d.*	50	7·44*d.*	10·50*d.*
Coke	Large	3·72*d.*	60	6·20*d.*	7·50*d.*
Coal	Small	3·72*d.*	40	9·30*d.*	11·80*d.*
Coal	Large	3·72*d.*	60	6·20*d.*	7·50*d.*
Anthracite . .	Small	3·83*d.*	55	6·97*d.*	9·61*d.*
Anthracite . .	Large	3·83*d.*	60	6·38*d.*	7·72*d.*
Fuel Oil . . .	Small	5·61*d.*	50	11·28*d.*	12·00*d.*
Fuel Oil . . .	Large	5·64*d.*	65	8·68*d.*	9·20*d.*
Town Gas . .	—	10·0*d.*	80	12·50*d.*	13·00*d.*
Electricity . .	—	14·66*d.*	95	15·44*d.*	15·54*d.*

The above figures are representative only and each case must be calculated independently, very careful consideration being given to the probable boiler efficiencies, labour involved, etc. It should also be noted that the basic price of fuel in Table I can vary very considerably according to locality and conditions of contract. The figure given in the two last columns of Table II can be taken to vary approximately *pro rata*, although this is not always strictly correct: for instance, in the case of a cheap solid fuel, with a large percentage of ash, the labour costs would be increased.

It must be remembered that the heat produced in the boiler, whatever fuel is used, is not, as a general rule, all introduced into the various rooms to be heated. There is a certain loss from the pipes conveying the heat to the required point, though this may be a very small percentage if the mains are properly insulated to prevent loss of heat.

There is one aspect of the matter that, owing to the possible great variation, is not fully taken into consideration in the above figures, and that is the excess of fuel that might be used, particularly in the case of solid fuel where the boilers have to be kept lighted, but not doing the full amount of useful work compared with the fuel consumed. It will be appreciated that this figure would vary with different classes of buildings and different fuels, but as between solid fuel and electricity, 15 per cent. might be taken as a fair average. It will be appreciated that there is also the question of cleanliness and the space occupied by the fuel to be considered.

FUEL CONSUMPTION.

In estimating the fuel consumption for any installation it should be remembered that in this country during a normal winter there are relatively few days when the full heating effect is required, the full boiler power only being necessary in case of severe weather, or in order to raise the heat quickly, say after a period of non-occupation of the building.

In practice it is found that the fuel consumption during an ordinary heating season works out at about one-half to two-thirds of the theoretical consumption if the installation were worked at full power during the period of occupation of the building.

As a guide, the fuel consumption (generally coke) may be taken, for office blocks and similar buildings, as 150 lb. per week per 100 sq. ft. of surface installed. This is equivalent to 134 tons per season of 30 weeks for every 1,000,000 B.Th.U.'s emission for which the system is designed. This is for heating only, and an allowance has generally to be added for hot water supply.

For large institutions, etc., the following figures may be taken as the average fuel consumption per annum for all purposes, including laundry and kitchen.

Mental and Public Assistance Institutions . .	$2\frac{1}{2}$ to 3 tons per person.
Hospitals	4 to $4\frac{1}{2}$,, ,, ,,
Sanatoria	$3\frac{1}{2}$ to 4 ,, ,, ,,

If a more close estimate of fuel consumption is required, the method usually referred to as 'degree days' is adopted. Taking the required temperature of the building as the datum level, the days on which the external temperature falls below this level are obtained from meteorological records, the mean temperature by which each of these days falls below the required level being summed up and compared with the number of days during which it is anticipated the heat will be required multiplied by the temperature difference for which the installation is designed. This will give a percentage approximating to the figures given above, and will, of course, vary according to the situation and degree of exposure of the particular building under consideration.

Size of Boiler-house required.

The following table indicates the minumum size of boiler-house for the various sized heating installations, and also the minimum fuel space.

Cubic Contents of Building.	Heating Surface at 20 sq. ft. per 1,000 c/ft.	B.Th.U.'s at 150 per sq. ft.	Boiler-house L. × W. × H. Ft.	Sq. ft. of Fuel Space Recommended.
50,000	1,000	150,000	10 × 6 × 7	30
100,000	2,000	300,000	10 × 8 × 7	60
250,000	5,000	750,000	14 × 9 × 8	140
500,000	10,000	1,500,000	14 × 13 × 9	280
1,000,000	20,000	3,000,000	28 × 13 × 9	570
2,500,000	50,000	7,500,000	30 × 20 × 12	1,400

The above sizes are given as a guide only, and the size and shape of the boiler-house will, of course, vary according to the type of boiler chosen. The sizes above are for the ordinary type of cast iron sectional boiler and are the minimum that should be allowed. They are for heating only, and in order to allow for hot-water boilers, etc., in addition, the space should be increased by, say, from 20 per cent. to 50 per cent. according to requirements.

When any method of ventilation is to be considered no rules, even approximate, can be given as the space required would vary according to the type and extent of the ventilating plant.

For institution work, where the plant would include steam boilers, calorifiers, pumps, etc., the total space required, including fuel storage space, may be taken as from 2 to 5 sq. ft. per head, according to the circumstances. The lower figure may be taken as an extreme case and represents an actual example where new boiler plant, etc., had to be accommodated in existing buildings.

As a further guide, the following examples are given of actual systems designed by the author.

Building.	Services provided for.	Cubic Contents of Building.	Space allowed for Engineering Equipment.		Total Space allowed.	Space for Central Station Equipment per 1,000 cu. ft. of Contents.
				sq. ft.	sq. ft.	
House (medium sized)	Heating and hot-water service.	24,600	Boiler-house and fuel store	200	200	8·0
House (large)	Heating and hot-water service.	100,000	Boiler-house Oil fuel store	400 120	520	5·2
Hospital (80 beds)	Heating and hot-water service.	350,000	Boiler-house and fuel store	820	820	2·3
Public building (medium sized)	Heating, hot-water service and some ventilation.	1,250,000	Boiler-house Fuel store Ventilation	750 280 350	1,380	1·1
Block of 50 residential flats.	Partial heating and hot-water service.	750,000	Boiler-house Oil fuel store	340 260	600	0·8
Public building (large)	Comprehensive engineering equipment, heating, ventilation, hot-water service, vacuum cleaning, artesian wells, and water-treatment plant, etc.	2,750,000	Boiler house Ventilation plant Oil storage Other equipment	1,500 3,000 1,500 2,000	8,000	3·0
Mental colony (750 patients)	Heating and hot-water service.	...	Boiler-house Fuel store	2,700 900	3,600	4·8 per person
Institution (380 residents)	Heating and hot-water service.	...	Boiler-house Fuel store	1,150 450	1,600	4·2 per person
Sanatorium (100 patients)	Heating and hot-water service.	...	Boiler-house Fuel store	970 126	1,096	10·96 per person
Municipal offices.	Heating, hot-water service and ventilation.	1,540,000	Boilers, etc. Fuel store Ventilation	1,035 500 750	2,285	1·5

In oil-fired installations it is usual to provide 6-ton tanks (1,500 gallons) for fuel storage as the oil supply companies usually deliver in 5-ton lots. For small plants, such as for private houses, delivery can be made in 2-ton lots, so that in these cases a 3-ton tank would be ample.

Special precautions are needed in storing oil, it being essential to stand the tank in a chamber sufficiently large and so constructed that it would hold the whole of the contents of the tank or tanks in case of leakage. Ventilation of the tank room should also be borne in mind, sufficient means being provided to enable this to be done mechanically if natural ventilation is not possible.

Adequate ventilation of the boiler house must always be provided by natural or mechanical means to ensure satisfactory draught.

CHIMNEY SIZES.

The following curves give some indication of the size of chimney required for the various sized installations:

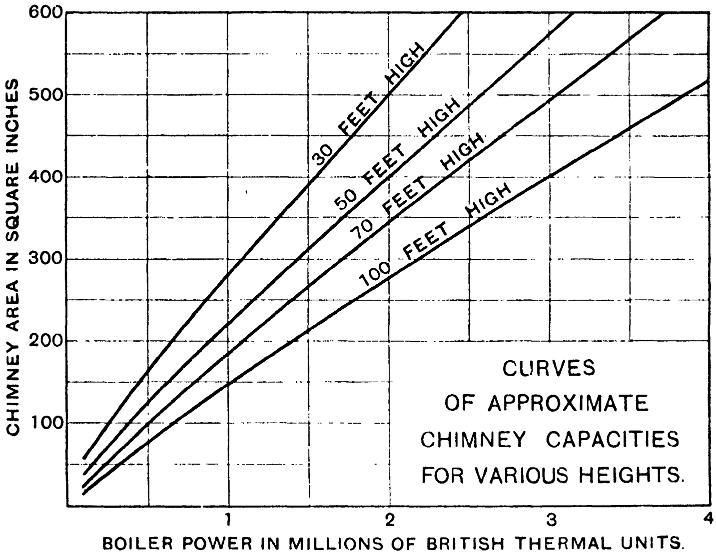

FIG. 1.

For all ordinary conditions, the sizes indicated will be found ample. Long horizontal flues and sharp bends should be avoided. Special attention should be paid to the surroundings at the top of the chimney so as to avoid any possibility of down-draught.

The sizes given by the curves are for the ordinary type of heating boiler, but if special boilers are used involving long travel of the flue gases through the boiler, or the resistance to flue gas travel is high for any reason, the heights given will need to be increased. For large installations the makers of the boilers proposed should be asked to state the draught required. Chimney and flue design is dealt with fully under Section XXVII, Part II.

Heating Systems.

The heating medium may be either water, steam, gas or electricity. In the case of water and steam, these may be distributed in various ways as follows:

Hot water	Low pressure gravity circulation. Low pressure accelerated circulation. High temperature hot water. (This is always accelerated with modern systems.)
Low pressure steam . . .	Condense through traps (live-steam or exhaust steam). Vacuum systems. Automatic vapour systems.

Hot Water.

Hot water heating systems may be designed either for circulation of the water by the gravity head set up by the difference in density between the water at flow temperature and return temperature, or for circulation by pumps, these latter being in nearly all cases of the centrifugal type.

Gravity systems are useful for small installations and where the height of the building is great in relation to the floor area. Owing to the small circulating pressure set up by the difference of temperature, pipe sizes are of necessity somewhat larger than in accelerated systems.

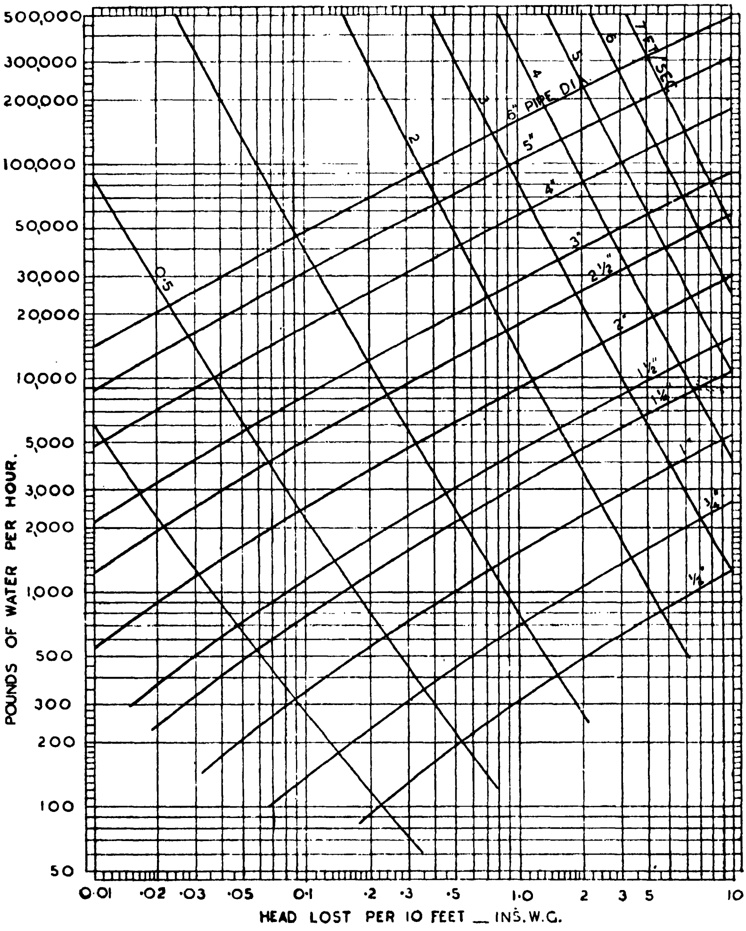

FIG. 2.

A temperature difference between flow and return of 30° F. may be taken as good practice, though to reduce the initial cost of an installation, pipe sizes are often reduced so that a much greater difference is found between flow and return. This, however, is not recommended.

Accelerated systems should be designed for, say, 15° F. to 20° F. difference between flow and return, and the pump head should be kept as low as possible consistent with reasonably sized mains, this making for low running costs. For medium-sized installations, the head might be 5 to 10 ft., whereas a head of 20 or 30 ft. or even more may be used in case of a central plant for, say, an institution with a number of scattered blocks to be served.

In favourable cases it is often possible to design the system so that normally the circulation is accelerated by a pump working at low head, but which is capable of working quite satisfactorily by gravity in mild weather, and also during times when the boiler is banked, as at night.

High temperature hot water systems are now frequently employed for factory installations, as they have certain of the advantages of the steam system without the disadvantages. Heat is provided through steam boilers which work at 150 to 200 lb. per sq. in., but steam is not drawn off from the boiler, the water in the boiler being circulated through the mains at the boiler temperature and pressure. This enables a very much larger temperature drop to be employed, a temperature drop of 80°–100° F. being common, which allows the pipe sizes to be kept smaller without introducing the necessity for a considerable amount of maintenance which results from the use of steam traps.

It is also possible to vary flow temperature between fairly wide limits by mixing some of the return water with the flow, so regulating the heat output from the installation to a larger extent than is possible from a steam plant. Particular care in design has to be taken to avoid trouble from water hammer due to accumulation of air or steam in the pipes and ample provision must be made for taking up movement of the pipes due to expansion.

Unit heaters are usually employed for distributing the heat, but if radiators are necessary, calorifiers have to be used to serve the radiators, as they will not stand the working pressure, and also it is not wise to run the high temperature hot water pipes in positions where persons can get in contact with the pipes, owing to the risk of burns.

Pipe Sizing.

The size of mains depends on the length, the quantity of water to be circulated and the head available to overcome friction. In the case of gravity circulations the available head is calculated by measuring the height of the centre of the least favourably placed radiator (known as the index radiator) above the centre of the boiler, and multiplying this dimension by the factor p, where $p = 0{\cdot}192\,(D_2 - D_1)$.

where p = circulating pressure in inches water gauge per foot of height.
D_1 = Density of water at flow temperature in lb./cub. ft.
D_2 = Density of water at return temperature in lb./cub. ft.

Table III gives the values of p for the temperatures usually obtaining in heating installations.

Table III.

Circulating pressure 'p' per ft. of height in inches W.G.

Diff. of Temp. ° F. between flow and return.	Flow Temperature °F.							
	120	130	140	150	160	170	180	190
10	0·029	0·032	0·034	0·036	0·039	0·041	0·043	0·045
15	0·043	0·047	0·050	0·054	0·058	0·061	0·064	0·067
20	0·054	0·060	0·066	0·071	0·075	0·080	0·084	0·089
25	0·067	0·074	0·081	0·087	0·093	0·099	0·103	0·109
30	0·078	0·086	0·094	0·101	0·109	0·116	0·122	0·129
35	—	0·098	0·108	0·117	0·125	0·113	0·141	0·149
40	—	0·109	0·120	0·130	0·140	0·149	0·159	0·168
45	—	—	0·132	0·145	0·156	0·167	0·177	0·187
50	—	—	0·142	0·157	0·171	0·182	0·193	0·205

In the case of accelerated circulations the size of pipe is limited by the allowable velocity of the water in the pipe, which it is usual to limit to a figure between 60 and 200 ft. per min. If the latter figure is exceeded there is a risk of noise occurring. The quantity of water circulating in both gravity and accelerated circuits is determined by the heat emission of the pipes and radiators on that particular circuit and the temperature drop allowed between the flow and return pipes. The weight of water to be circulated is calculated as follows:

$$\text{Weight of water per hour} = \frac{\text{Emission B.Th.U./hr.}}{\text{Temperature drop.}}$$

Having estimated the head available to overcome pipe resistances the pipe size can be estimated from the following equation by dividing the head available by the total length of the pipework and the equivalent length of fittings.

$$p = 174 \cdot 2 \, f \, \frac{w^2 v L}{d^5} \quad \text{where } f = 0 \cdot 0054 + 0 \cdot 375 \, \frac{\mu v}{Vd} \quad \text{(according to McAdams and Sherwood).}$$

and p = pressure lost in lb. per sq. in. d = internal diameter of pipe in ins.
w = water flowing in lb. per sec. μ = viscosity in centipoises.
L = length of pipe in ft. V = velocity in ft. per sec.
v = volume of 1 lb. of water in cub. ft.

Fig. 2, based on the above, gives the resistance in ins. W.G. per 10 ft. run of pipe.*

All pipe fittings such as bends, tees, valves, etc., and also the boiler and radiators set up a resistance to water flow. In many normal installations this additional resistance may be allowed for by adding 30 per cent. or 50 per cent. to the measured length of pipework. Where a more accurate estimate is required of the equivalent length to be added to the pipework the factors in the following table should be multiplied by the diameter of pipe in inches.

Fittings.	Factor Multiplied by Dia. of Pipe in Ins. equals approx. equivalent length in Ft.
Gate valve	0·65
Easy bend	0·9
Round elbow	1·8
Straight through tee	0·9
Straight through reducing tee	1·8
Close return bend	2·7
Tee through branch	3·5
Tank, radiator or boiler	3·5
Angle valve	15·0
Globe valve	30·0

Steam Heating Systems.

Only in rare cases is high-pressure steam used for heating. Generally the pressure used is under 5 lb. per sq. in., and in so-called vacuum systems the pressure may be below atmospheric.

In steam heating the temperature of the surface depends on the steam pressure and this may be obtained from the table on p. 3, which gives the temperature and other properties of steam at the pressures usually obtaining in the steam heating systems.

It is usually accepted that the emission from heating surface varies approximately as the 1·3 power of the temperature difference between the heating medium and the surrounding air. This is a very useful factor as, within reasonable limits, the heat transmission can be obtained for any temperature difference.

It will, therefore, be seen that with steam heating the surface required is much less than with hot-water heating. For instance, to provide an emission of 100,000 B.Th.U.'s per hour to a room at 60° F. the comparative amounts of surface required would be approximately:

With water at 160° F. : 660 sq. ft. of surface.
With steam at 212° F. : 390 sq. ft. of surface.

Steam heating, while having some advantages over hot water, such as less liability of damage from frost in case of intermittent heating, damage by water in case of a leak, is not, except possibly in industrial work, generally so suitable for our very variable climate as hot-water heating.

Steam heating may be divided into two main classes:

1. Low-pressure systems generally in which the condensate is returned by gravity to the boiler plant. Alternatively the condensate may be collected in a hotwell and pumped into the boiler.

2. Vacuum systems in which the condensate mains are connected to a pump which exhausts the air and draws away the condensate.

Low-Pressure Systems.

Ordinary low-pressure systems may be divided into single-pipe and two-pipe systems.

* Chart prepared by permission from data published by the Institution of Heating and Ventilating Engineers.

In the single-pipe system the steam and condensate are carried in the same pipes, often in opposite directions, so that unless great care is taken in designing the system, trouble may be caused by noise set up by water-hammer.

In two-pipe systems the condensate is carried in separate pipe lines and run down into a wet return, or fitted with an automatic water seal at the radiator outlet.

Size of Pipe.—The size of pipe to supply a given amount of heat at a given point depends on the length, initial pressure and the maximum loss of pressure to be allowed.

The results shown in fig. 3 have been calculated for about 1·3 lb. initial gauge pressure and 3 ins. water gauge drop and are for the two-pipe system. For single-pipe systems multiply B.Th.U.'s by 0·5.

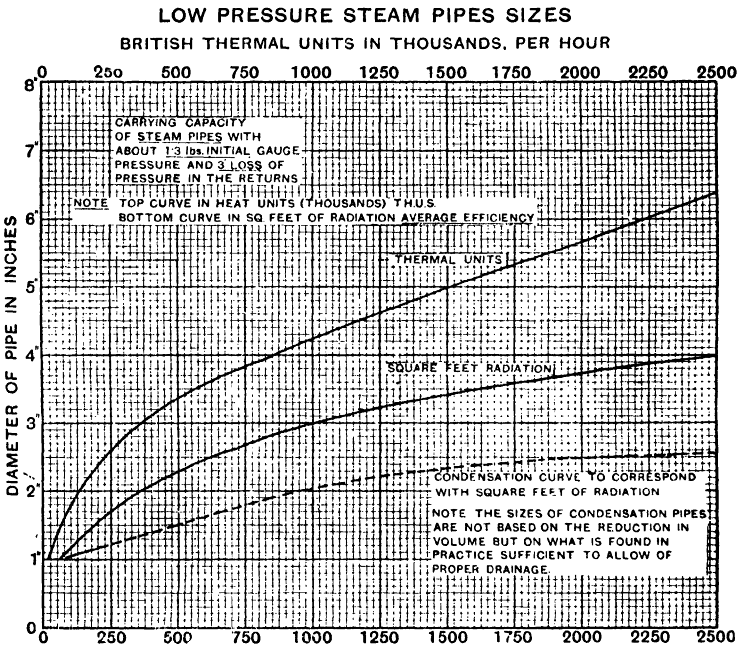

FIG. 3.

VACUUM SYSTEMS.

One of the objections to the ordinary gravity steam installation is the difficulty of displacing the air in the radiators and at the same time controlling the heat. This may be overcome by attaching a system of piping to the air valves connected to a small exhausting pump which draws away the air and forms a partial vacuum. Another way is to attach all the condense mains to a pump which will exhaust the air and draw away the condensate. This latter method is known as the 'Vacuum System.'

The piping is much the same as in an ordinary gravity steam system except that the mains are rather smaller and the condense pipes much smaller.

Owing to the thorough circulation of steam, the radiating surface has a higher efficiency per sq. ft. per degree F. difference. It should be noted, however, that this does not materially affect the fuel efficiency.

The success of a vacuum system depends to a large extent on the proper working of the traps which are fixed on the radiators or wherever condensate is likely to collect.

Hot Water Supply.

The quantity of hot water required for domestic use, or in institutions, asylums, etc., may be taken as from 20 to 25 gallons per head per day. In hospitals and sanatoria the quantity is much more, varying from 30 to 40 gallons per head per day.

For small domestic installations, the range boiler will generally supply the needs, but this type of boiler is very inefficient and in all but the smallest houses might well be replaced by an independent boiler.

With independent boilers care should be taken to see that the boiler has ample surface for its duty, otherwise inefficiency will result. In hard water districts the boiler should be periodically inspected and cleaned out so that the deposit which has collected is removed.

It is recommended, where the water is hard, that the indirect method of heating the water should be employed. In this method the hot water supply, *i.e.* the water actually drawn off from the taps, is heated in an indirect cylinder or calorifier, the primary of which is in turn heated by an ordinary heating boiler. Thus the primary water, *i.e.* the water actually in contact with the hot surface of the boiler, is not changed, and the amount of deposit is limited. In addition, the heating surface in the indirect cylinder or calorifier is at a much lower temperature than that of the boiler plates with which the water is in contact when heated directly and there is much less tendency for scale to form on the surfaces.

Where steam, either live or exhaust, is available, steam calorifiers are the most common means of providing the hot water supply, and lend themselves to easy thermostatic control. (See notes on ' Use of Exhaust Steam ' given on p. 673.)

In small or medium-sized installations, the water may be heated by gas or electricity, the system being entirely automatic. These two methods are generally found to be too expensive for large installations, but they do, however, provide an easy and convenient means of obtaining small quantities of hot water at irregular intervals.

Boilers and Boiler Power Required.

Boilers for direct heating of the water should be as simple as possible and designed so that all points are easily accessible for cleaning, especially in districts where the water is at all hard. In soft water districts special attention should be paid to the material of which the boiler is constructed. In some places, the only material suitable for the boiler, in fact for the whole system, is copper.

In determining the size of the boiler required, it may be assumed in all ordinary cases that the water will need to be raised from 50° F. to 150° F. Thus, if the quantity of water required is Q gallons, the heat required in B.Th.U.'s per hour, is

$$\frac{10Q \times 100}{T} + \begin{array}{c}\text{Radiation losses from storage}\\ \text{cylinder and pipework.}\end{array}$$

where T is the time in hours allowed for obtaining the required temperature.

An ordinary hot water boiler will transmit, say, 2,500 to 7,000 B.Th.U.'s per hour per sq. ft. of surface, the lower figure being for the secondary surface, and the higher figure for the fire-pot surface. An average figure of 5,000 B.Th.U.'s per sq. ft. per hour may be taken for ordinary purposes.

In large systems the load on the boilers on account of the hot water supply may be taken as the equivalent of 3 gallons per head per hour (150° F.) provided ample storage is arranged to even out the demand. This is approximately equivalent to 3 lbs. of steam per head per hour, where steam is the heating medium.

Storage and Distribution System.

It cannot be too well stressed that whatever system is employed for heating the water, ample storage should be allowed. This provides a good reserve in case of heavy demands on the system, and has the advantage that the load on the boilers is levelled out, tending towards higher efficiency.

For a private house with, say, two baths and six or seven other draw-offs, the storage should be, say, 75 gallons. In institution work a good figure for hot water storage may be taken as 5 gallons per head (minimum).

All storage vessels and circulations should be adequately lagged to prevent heat losses. For the same reason, the temperature at which the water should be circulated should not exceed 140° F. to 150° F., which is ample for all normal purposes, and in large systems where really hot water may be required at certain points—say in the kitchen for washing up greasy utensils—it is often advantageous to boost up at these points with gas, electricity or steam, maintaining the general supply at the above temperature. To guard against undue wastage of water, the circulations should be run as near the actual taps as practicable, thus avoiding long draw-off pipes with ' dead ' water which must be run to waste before hot water is obtained.

The following draw-off rates may be taken as average figures in determining pipe sizes:

Bath (private)	5 gal. per min.
Bath (public)	8 ,, ,, ,,
Sink	4 ,, ,, ,,
Lavatory basin	1½ ,, ,, ,,
Shower nozzle (spray type)	2 ,, ,, ,,

In designing the circulation for hot water supply it should be remembered that the pipes must be sized to supply the quantity of water necessary to meet the maximum demand at the taps. This maximum demand in the case of a small installation will be when all taps are open together, but in larger installations the simultaneous demand at any one time will be less than the possible maximum and it is usual to make suitable allowance for this according to the size of installation. Fig. 4 gives an approximation for this purpose.

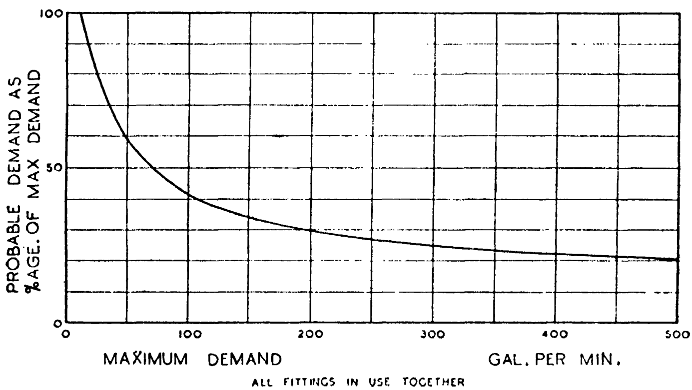

FIG. 4.

The flow of water to the taps will be along both the flow and return pipes, but since it is desirable to limit the admixture of the cooler return water as much as possible it is usual to size the flow on the assumption that this pipe will supply 75 per cent. of the demand and to size the return to take care of the flow required to make good the heat losses from the system when no draw-off is taking place. The flow from any tap depends on the difference in level between the point at which water is drawn off and the level of the water in the cold water storage tank feeding the system, and also on the loss in pressure due to friction of the water flowing in the pipes including the cold feed from the storage tank. This basis is used for sizing the flow. The return is sized on the heat loss from the system in a similar manner to that employed for a heating system. The circulation may be by gravity or accelerated by a pump according to conditions and the size of installation. In some cases, where the feed tank cannot be placed high enough booster pumps may be required to give the necessary delivery at the taps. Certain economies in the size of pipes can sometimes be made by the employment of head tanks arranged to take care of momentary peaks.

Use of Exhaust Steam.

The use of exhaust steam from prime movers for such purposes as heating or hot water supply, etc., is to be recommended wherever possible, as this allows of the latent heat in the steam being utilised, which cannot be used for power production.

The reason for the relatively low thermal efficiency of the electrical stations throughout the country, supplying the grid, is largely the non-utilisation of the exhaust steam, and it is possible for a small generating plant, such as that in a public institution or industrial concern where exhaust steam can be used, to have a very much higher thermal efficiency than the largest condensing super-power station.

The exhaust steam can either be taken direct from the engines for direct steam heating, or it can be used in calorifiers to heat water which is pumped round the heating systems.

In many institutions, hotels, etc., it is found that there is practically no difference in their annual coal consumption whether electric current is purchased from outside or generated on the

premises, as there is a demand for heat all the year round which can be met by the exhaust steam from the power plant, so that the extension of this system to general domestic heating from the existing small power plants would enable these small power plants to run at a greater efficiency than any large condensing plant.

These combined systems are of great use and lead to economical working in such cases as laundries, works where process steam is required, hotels, institutions, etc., where it is often an economical proposition to generate the electric supply, the exhaust being utilised for such purposes as heating, hot water supply, etc. In these cases, the power or electric current may be often looked on as a bye-product of the steam-raising plant, the actual cost of the energy used in producing power or current being extremely small. The chief factor in many cases is the interest and sinking fund and capital outlay involved. Even so, taking all costs into account, including the extra labour involved, electricity can often be generated at, say, 1½*d*. per unit. Each case, of course, must be gone into on its merits, but this may be taken as a figure quite often obtaining in actual practice.

Taking 1 sq. ft. of steam radiation as requiring 250 B.Th.U.'s per hour, 1 lb. of steam per hour will supply about 4 sq. ft. of radiation. A rough and ready rule for finding the radiation which may be supplied by any engine is to multiply the horse power by 130.

When exhaust steam is employed for heating, it is necessary to extract the grease by means of a separator, so placed as to intercept the grease before the steam enters the heating mains unless the engine is designed to run without cylinder lubrication or other means are taken to ensure clean steam. Usually it is necessary to have an outlet to atmosphere which is closed by a back pressure valve so that any steam which cannot be absorbed in the heating or other system will be discharged to atmosphere without building up back pressure. The back pressure valve may be set for, say, 5 lb. per sq. in., to ¼ lb. per sq. in., the latter pressure only being permissible where a vacuum return line is maintained as in the vacuum system.

SECTION XXXIV

PART II

VENTILATION.

(Revised by L. Copeland Watts, M.I.Mech.E., P P.I.H.V.E., A.C.G.I.)

Amount of Air necessary for Ventilation.

The air required for ventilation can be obtained in one of two ways: (*a*) natural ventilation, and (*b*) mechanical ventilation. While natural ventilation is quite satisfactory for small rooms not very thickly populated, or in cases where there is a large window area which can be kept open, in buildings such as theatres and cinemas, offices and similar buildings where the density of population is great, mechanical ventilation is usually employed. For theatres and cinemas there are usually local regulations to be complied with stating the quantity of air which must be provided per person per hour. The L.C.C. Regulations lay down that the minimum quantity of fresh air to be provided per person is 1,000 cu. ft. per hour. In certain classes of buildings, such as public swimming baths which are used as public halls or dance halls during the winter, this quantity may be reduced in certain cases to 750 cu. ft. per hour. It can be taken that these figures are the absolute minimum which should be provided, a more satisfactory quantity being from 1,800 to 2,000 cu. ft. of fresh air per person per hour. In cases where complete air conditioning is installed and cooling is effected in the summer, while this quantity of fresh air should still be introduced, the total quantity including recirculated air should preferably be in the neighbourhood of 3,000 cu. ft. per person per hour.

In the case of offices where the number of occupants in the room is frequently unknown at the time the installation is designed, it is usual to base the air quantities on a rate of change in which case not less than three changes per hour should be provided.

Distribution of Air.

It is not sufficient merely to introduce the requisite quantity of air into a room, it is important that it should also be well distributed so that every part of the room obtains its proper share without draught. This needs considerable care when designing installations dealing with large quantities.

When mechanical ventilation is employed the air is moved by fans, these usually being situated at some point remote from the room or rooms being ventilated, the air to and from the rooms passing through ducts connecting the gratings with the fans.

There are three methods of mechanical ventilation employed, the particular method depending on circumstances:

(*a*) *Mechanical extract only.*—Inlets are provided at a low level, preferably behind radiators, the air being extracted by means of a fan at high level. This method should not be employed in halls seating over 500 people.

(*b*) *Mechanical inlet only.*—Inlets are provided at a low level or about 6 ft. above floor level. A common distribution is one-third of the total area of gratings at low level and two-thirds at 6 ft. up. Outlets are provided through the walls at high level or through the ceiling. This method is employed when fresh air from outside is not otherwise obtainable.

(*c*) *Both mechanical inlet and extract.*—In this case air is drawn in and extracted by fans. It is usual to extract approximately 75 per cent. of the amount of air introduced by the inlet fan. As to the situation of the inlet and extract gratings, this depends very much on the design

of the building and the most convenient position for them. This system, which is frequently referred to as a 'balanced system,' is employed in underground rooms, theatres and other rooms where open windows are undesirable as, for instance, in noisy or dirty situations.

There are three main systems of air distribution employed :

(1) *Upward Ventilation.*—In this case the fresh air is introduced through gratings at low level, as described in (*b*) above, the air being extracted through gratings at high level, or in the ceiling over.

(2) *Cross Ventilation.*—In this case the air is introduced through gratings along one side or end of the hall, the extract gratings being provided in the opposite walls. In this case it is usual to arrange for the gratings to be approximately 6 ft. above floor level.

(3) *Downward Ventilation.*—The downward system of ventilation is often adopted in theatres and cinemas ; the air is introduced at high level, commonly in the ceiling, and extracted through a large number of well distributed extract outlets at low level. These are often of the mushroom type fixed under seats. Downward ventilation is particularly advantageous when air is introduced at a temperature lower than room temperature, in order to give a cooling effect in the summer, the incoming air thus falling gradually and being well diffused before reaching the occupied zone, which tends to avoid a feeling of discomfort and complaints of draught.

Where circumstances allow, it is often found advantageous to arrange the distributing ducts in such a way that the direction of the air currents in the room can be reversed, the particular direction of air flow depending upon outside atmospheric temperatures. The rate of air movement through the room should, of course, be kept very low in order to avoid a sensation of draught. It is, however, advantageous to be able to direct a perceptible movement of air through a room when the external temperature is high in cases where cooling is not provided. A stream of air moving at about 600 ft. per minute gives a decided feeling of comfort when the temperature of the air is above 75° F.

In certain types of building where it is essential to keep the floor space clear, as, for instance, dance halls and skating rinks, high velocity jets are sometimes employed, arranged to throw streams of air across the room at a little above head level, so inducing an air movement below, the air velocity being so arranged that the whole of the air throughout the room is disturbed and changed.

Should it be necessary to trace the air movement in a room, this can conveniently be done by blowing air through HCl and NH_4OH, the vapour so formed causing, when mixed, a dense white smoke which is at atmospheric temperature. Alternatively, titanium tetrachloride can be used. If a glass rod is dipped into the liquid and held in the air it gives off a dense white smoke also at atmospheric temperature. Since the white smoke so formed is approximately at air density, the drift indicates the direction and intensity of the air currents.

Air-Filtering, Washing and Conditioning.

It is always desirable and frequently essential that the air should be as free from dust and impurities as possible, This dust can be removed by filters and air washers. There are several types of air filters obtainable, but they can be divided into three main groups :

(i) *Dry Filters.*—These consist of a series of perforated plates arranged so that the perforations are staggered, the plates being covered with a sheet of wadding on the up-stream side for the better collection of the dust. The filtering effect is dependent on the number of plates. To clean, the filter unit is detached from its frame and shaken.

(ii) *Fabric Filters*—in which air passes at low velocity through muslin, canvas or cotton wool specially made for the purpose and stretched on frames or over supports, designed so as to give a large area of fabric compared with the space occupied by the complete filter unit. The resistance of this type of filter increases as dust is deposited and the filter has either to be cleaned or the fabric renewed periodically. With low velocities through large areas of suitable fabric, high efficiencies are obtained.

(iii) *Viscous Fluid Filters.*—In these the air passes over a series of plates or troughs coated with a viscous fluid, usually a special oil, to which the dust adheres. Certain designs employ steel wool or other fillings, arranged so as to ensure that there is no direct passage for the air through the filter. These also are coated with similar viscous fluids. To clean, the filter unit is washed in hot, strong soda water and then dipped in the viscous fluid and allowed to drain before replacing.

A development of this type of filter is the continuous viscous filter in which the units are mounted on a continuous band arranged so that each unit in turn passes through an oil bath which removes the dirty oil and replaces it with clean oil, usually hand operation being employed to rotate the filter at intervals, say, every day or two.

Air Washers.—These commonly consist of a series of fine water sprays through which the air passes mixing thoroughly with this finely divided spray, afterwards passing over a series of eliminator plates which collect the surplus water together with the dust.

The use of dry or viscous filters removes the dust without altering the temperature on humidity of the air, while the air washer varies both the temperature and humidity thus

making it unsuitable for certain purposes although it is frequently advantageous, especially when applied to the ventilation of halls and theatres.

The efficiency of dust removal by air washers is not usually very high, particularly if the dust is of an oily or greasy nature. When a greater cleaning efficiency is required than can be obtained with an air washer alone, it is common to place a series of dry or viscous filters after the air washer to remove a proportion of the dust remaining in the air after leaving the washer.

Air Cooling.

The endeavour to produce a pleasant and healthy inside atmosphere at all times of the year, whatever the outside conditions may be, has received a good deal of attention of late years. If, however, it were 90° F. outside, it would be very unwise and actually uncomfortable for people to go into a temperature of, say, 60° F., or even 70° F. In this case, the reduction of the dry bulb temperature by about 10° F., together with a perceptible air movement, would probably give rise to a marked degree of comfort. The most desirable relative humidity for public halls and offices is between 50 per cent. and 60 per cent.

Air can be cooled by an air washer, but the relative humidity will always rise. In a washer using recirculated water, the heat content will not be substantially changed although a certain cooling effect can be obtained with a consequent rise in relative humidity. The wet bulb temperature is unaffected by this method, so that the cooling is limited by the initial wet bulb temperature and will in practice always be a few degrees above this. Actually it will be found that the dry bulb temperature can be reduced by about 75 per cent. of the difference between the wet and dry bulb temperatures.

When artesian well water or some other water having a temperature of 52° F. is obtainable, the air can be cooled to about 57° F. with a consequent reduction in the vapour content of the air should the initial dew-point be above 57° F., which is most probable in hot weather. The air will then be saturated.

When air is required with a lower temperature than can be obtained by the air washer, refrigeration will have to be employed. Cooling air is far more expensive than heating. For general ventilation, the air may be cooled from 10° F. to 15° F., but for industrial purposes, when it is required to have complete control over the relative humidity and temperature, it is usual to cool the air to 35° F. The amount of brine to be circulated should be calculated on a drop of 3° F. The specific heat of brine may be taken as 0·82 and in calculating the heat required for the reduction in temperature the condensation of the vapour must not be forgotten. The heat in British Thermal units per hour, divided by 12,000, will give the size of plant required in tons of refrigeration per day of 24 hours.

The heat exchange in cooling or heating air over a given range of temperature is not materially different, provided the dew-point is not reached. Should, however, the initial humidity be such that the dew-point is reached in the cooling, another very important factor is introduced, a portion of the aqueous vapour being condensed and giving up its latent heat in the process. The British Thermal Units involved in the heat exchange may be ascertained by the following, which is accurate enough for all practical purposes and shows the various steps involved :

$$\begin{array}{ccccc} \text{SECTION A.} & & \text{SECTION B.} & & \text{SECTION C.} \\ U = L_e(W_1 - W_2) & + & S_v(T_1 - T_2)W_1 & + & S_a(T_1 - T_2) \end{array}$$

where

T_1 = initial dry bulb temperature ;

T_2 = final „ „ „

W_1 = weight of aqueous vapour per lb. of dry air at initial temperature T_1 ;

W_2 = „ „ „ „ „ „ „ „ „ „ final temperature T_2 ;

L_e = mean latent heat of vaporisation or condensation at initial dew-point, and T_2

S_v = specific heat of vapour ;

S_a = specific heat of air ;

U = B.Th.U.s to cool 1 lb. of air from T_1 to T_2 ;

Basic figures to be taken for this and other equations :

S_v = specific heat of aqueous vapour = 0·444 ;

S_a = specific heat of air = 0·2400.*

L_e = latent heat of vaporisation varies from 1073·4 B.Th.U.s per lb. at 32° F. to 1052·3 B.Th.U.s per lb. at 70° F.

Section A is the heat required to be extracted to condense the water vapour.

Section B is the heat required to be extracted to reduce the temperature of the water-vapour content of the air and is so small that it can usually be neglected.

Section C is the heat required to be extracted to cool the air from T_1 to T_2.

* 0·238 was at one time the accepted figure for specific heat of air and will be found in many textbooks, but 0·2400 is now accepted as the more correct value for the temperatures usually obtaining in air conditioning work.

Humidity.

Saturated Air.

Air is said to be saturated when it has mixed with it the maximum possible amount of vapour. The maximum amount of vapour in a given volume is dependent on the temperature.

Dew-point.

This is the temperature corresponding to saturation (*i.e.* 100 per cent. humidity) for a given weight of vapour per cu. ft. Cooling of any vapour beyond dew-point results in condensation of part of the vapour as moisture. If a mixture of air and water vapour is cooled to dew-point the air becomes saturated—relative humidity 100 per cent.—and any further cooling causes part of the vapour to separate out as moisture, giving up its latent heat.

Wet and Dry Bulb Hygrometer.

This instrument provides a ready method of determining the relative humidity, dew-point, etc., of the air. It consists of two ordinary thermometers, the bulb of one of which is kept moist by means of a loose cotton wick which is either moistened before use or which dips into a vessel of water. The most reliable readings are obtained when the air is moving quickly relative to the instrument and the sling psychrometer is a useful means of obtaining the necessary air movement. This instrument consists of a frame with the two thermometers mounted thereon which can be whirled round rapidly. The thermometers should be whirled for about half a minute and the readings taken. This should be repeated several times until two successive readings agree.

The hygrometric chart, fig. 1, gives the relative humidity, dew-point, and grains of water vapour per cub. ft. corresponding to different thermometer readings. For instance, if dry bulb

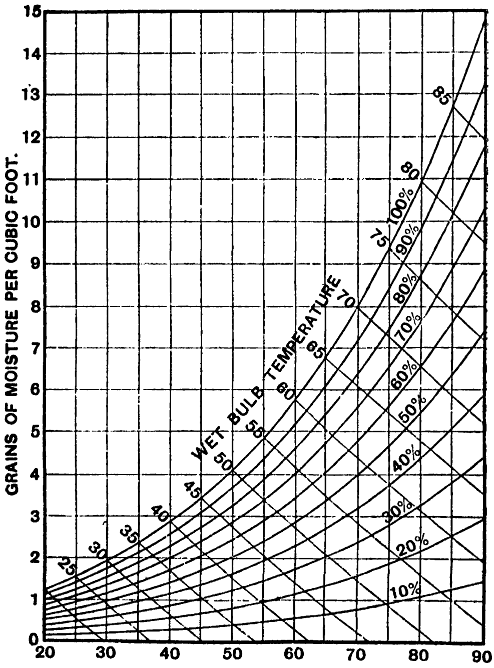

FIG. 1.

temperature is 70° F. and sling wet bulb temperature is 60° F., the relative humidity is 55 per cent., the dew-point is 53° F., and the weight of vapour per cub. ft. is 4·4 grains. Vapour in a cub. ft. at saturation point is 7·98 grains at above temperatures.

Velocities of Air Flow for Mechanical Ventilation and Flow of Air Through Ducts.

Where silence is essential, the velocities of flow of air in ducts must be kept low, the ideal velocity being from 10 to 15 feet per second, and on no account exceeding 20 feet per second. For factory work speeds up to 30 feet per second are allowable, but this velocity should not be exceeded. In general, the outlets to the rooms (if at low level) should be of such an area that the air issues at a velocity of from 1½ to 3 feet per second, as such velocities do not give rise to a sensation of draught. In certain circumstances, however, such as during hot weather, it may be found desirable to direct a flow of air across a room at a velocity of 10 to 15 feet per second, this movement giving a feeling of coolness. (See 'Effective Temperature,' p. 662.) The following table gives the permissible velocities for different parts of the ventilation system. The lower figure refers to ventilation where silence is desired, and the higher gives the maximum permissible for factories, etc.

Fresh air intake .	500 to 800 ft. per min.	Main ducts . .	800 to 1,200 ft. per min.
Heating battery .	800 ,, 1,500 ,, ,,	Branch ducts .	600 ,, 900 ,, ,,
Filter . . .	150 ,, 350 ,, ,,	Registers . .	90 ,, 180 ,, ,,
Washer . . .	300 ,, 500 ,, ,,		

The flow of air through a building resembles an electrical circuit, the inlets, outlets, and ducts acting as the resistance, and absorbing some of the aeromotive force. *To ensure an even flow in various ducts requires considerable care*; the resistance must be low, as the initial force in ventilation is small, usually equal to about 0·25 in. of water gauge. In natural ventilation it is much less than this.

In order to obtain an even distribution of air throughout the system, the design of the ducts is very important. Changes in direction and section should be as gradual as possible, particular care being taken to avoid sudden changes. The finish of the ducts should always be of the best, as roughness and irregularities increase immensely the resistance to the flow of air. The ducts are usually made of galvanised iron or in builders' work. When made by the builders the ducts should be lined with glazed bricks, or, if this is too expensive, finished with Keene's cement or some similar hard, smooth finish. It is always advisable to whitewash the latter, as the presence of dust is then easily noticed and more likely to be removed. The importance of the foregoing will be appreciated when it is realised that in mechanical ventilation where silence is essential the fan should not work against a resistance exceeding 1 in. W.G. and in other general work it is advisable not to exceed 2 in. W.G., except for dust extraction and similar industrial processes.

There is still a need for further research work in connection with the flow of air in ducts, but the following will be found a useful formula for the flow of air through galvanised iron pipes:

$$C = 39d^{2\cdot5} \Big/ \left(\frac{L}{H}\right)^{\frac{1}{2}},$$

where,

C = cubic feet of air per minute; L = length of pipe in feet;
d = diameter of pipe in inches; H = drop of pressure in inches of water.

The values derived from this formula are shown more conveniently in fig. 2.

For resistance in ducts of other materials than galvanised iron, multiply the result obtained from the diagram or by the above formula by the following factors:

Smooth concrete . . . . 1·5 Brickwork . . . . . . 2·0

When arriving at the total resistance in a duct, allowance must be made for bends and loss due to entry and egress at registers. These losses are often assessed by calculating the length of ducting which would set up frictional resistance equivalent to the local resistances, in a similar manner to pipework on a heating system. The loss of a sharp elbow varies from 30 to 60 diameters, a smooth bend 5 diameters and a usual register 80 diameters.

To obtain the total head against which the fan has to work, the velocity head must be added to the resistance in the duct; this is obtained from the following formula:

$$h = \frac{6D \cdot v^2}{gk},$$

where,

v = velocity in ft. per sec.; h = velocity head in. W.G.;
g = 32·2 ft. per sec./sec. D = density of air at temperature required
k = density of water = 62·4 lb. per cub. ft. = 0·0749 for dry air at 70° F.

All the above is based on circular pipes. In the case of rectangular pipes, find the equivalent circular pipes to give equal discharge for equal resistance from the following formula, and then use fig. 2 to find the resistance to flow:

$$D = \sqrt[5]{3\cdot25\,\frac{A^3B^3}{A + B}},$$

RESISTANCE OF FLOW OF AIR PER 100 LINEAL FEET OF CIRCULAR GALVANIZED IRON TRUNKING.

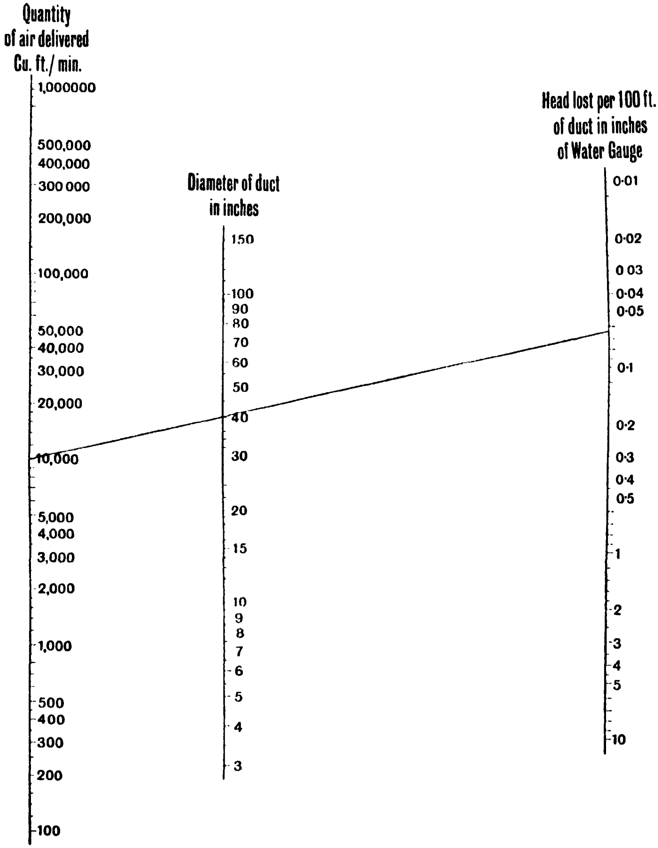

FIG. 2.

EXAMPLE: To find the loss of head in a 40-in. diam. duct carrying 10,000 cu. ft. of air per minute, lay a straight edge as shown connecting 10,000 cu. ft./min. and 40-in. diam., reading the loss of head 0·064 in. W.G. per 100 ft., on the right.

where,
A = long side of rectangular pipe ; B = short side of rectangular pipe ; D = dia. of equivalent round pipe.

This equivalent diameter can conveniently be found by means of fig. 3.

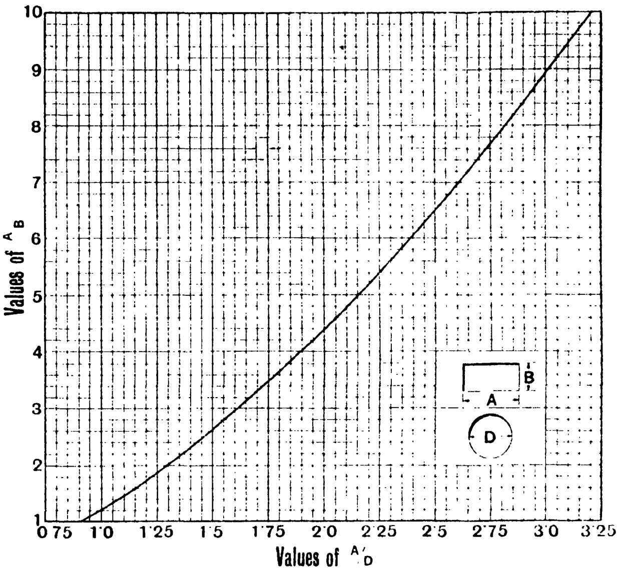

FIG. 3.

Diagram for obtaining equivalent Diameter of Round Duct carrying the same amount of air for the same loss as a Rectangular Duct.

Early consideration should be given to the position and size of ducts when mechanical ventilation is to be employed in a building.

Assuming a building in which there are, say, 3,000 people, and taking the L.C.C. requirements of 1,000 cu. ft. per hour, this means about 830 cu. ft. per second. The velocity permissible in the ducts will depend to some extent on their length, but 10 to 15 ft. per second may be taken as a good maximum average. This means that the inlet and distributing duct should have an area of not less than 55 sq. ft. As a streamline section must be maintained, it follows that where a change of direction in a duct of this size takes place, considerable space is taken up, and unless provision has been made for same, difficulties may be encountered. Steelwork is often a very important factor, especially in connection with the vertical subsidiary ducts, and is very difficult to modify ; this trouble can only be avoided by close collaboration between the various parties concerned in the early stages of the building.

It must be remembered that high air velocities and high speed fans are a source of trouble and expense however attractive it may be at the time to install small trunks that are easily adapted to the building.

Movement of Air by Fans.

The choosing of a suitable fan is a most important factor in any scheme of mechanical ventilation.

There are two distinct types of fans used for this work : the propeller and centrifugal, one similar to a ship's propeller, and the other more like a paddle wheel.

A propeller is a very efficient and useful fan if used in the proper way, that is, either with free inlet and outlet, as, for instance, when fixed in a window or wall without any trunking attached, or with short trunking of ample size, causing very little resistance head.

In the average building a fan must run at a low speed to avoid noise. At this speed the output and efficiency of a propeller fan fall off very considerably against resistance, as will be

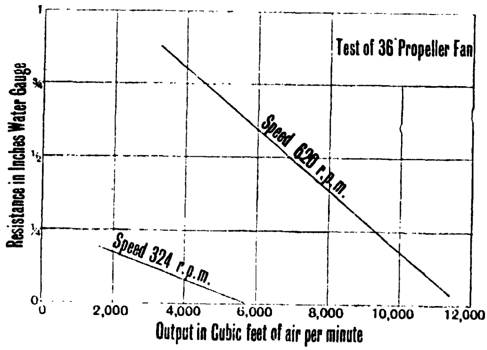

FIG. 4.

Diagram showing how the volume of air delivered by a propeller fan falls off with increased resistance.

seen from fig. 4. For factory and similar work where noise and extra power do not matter, the fan may be run at a much higher speed, in which case it can be used at a higher water gauge, see fig. 4, but even then the economical limit is soon reached. It must be remembered also that as the quantity of air decreases, due to resistance, the power increases.

During recent years, propeller fans with blades shaped to an airfoil section, have been marketed. This design of fan is known as the axial-flow type. They are more suitable for use with higher pressures than the normal propeller fan, they are more efficient, except under free air conditions, they have a non-overloading power characteristic and are quieter for equivalent size and speed.

The centrifugal fan can be used up to any reasonable pressure, but for general ventilation, where absence of noise and economy of power is desired, it is good practice not to exceed about 1 in. total head (resistance head + velocity head), the filters, heaters, ducts, etc., being designed accordingly.

In the usual type of centrifugal fan (generally called a multi-vane) the vanes or blades are curved forward (in the same direction as rotation) the resultant fan characteristic being that when the static pressure drops the volume of air increases and the power also increases, so that there is danger of overloading the driving motor unless this has sufficient margin of power and proper care is taken in calculating the resistance of the system to which the fan is to be coupled.

If the vanes are curved backwards the fan is given a non-overloading characteristic, *i.e.* a reduction in resistance does not produce a substantial increase in volume and the driving motor is not overloaded. With any given system, when varying the speed of a centrifugal fan, the quantity of air delivered varies directly as the fan speed, the resistance varies according to the square of the speed and the power taken according to the cube of the speed.

Movement of Air other than by Fans.

As the air in a flue such as a chimney or outlet duct from a warmed room is at a higher temperature than the outside atmosphere, its density is less, and the tendency is for it to rise. The resulting velocity of flow varies within wide limits, but is theoretically given by

$$V = 480 \sqrt{\frac{h(T - t)}{t + 460}}$$

where,

V = velocity of air in feet per minute;	T = temperature of heated air °F;
h = height of flue in feet;	t = outside temperature °F.

The actual velocity is considerably lower in practice, and the result from the above formula should be multiplied by 0·25 to 0·6, according to size, shape, and materials.

In addition to the movement of air due to difference of temperature, the wind has a considerable aspirating effect on a properly designed ventilator.

Heating units such as gas jets, electric heating, steam or hot water coils, are sometimes used for the purpose of causing an up-draught. These should never be used if any other method is available, as they are very inefficient and costly in up-keep, costing, in the case of steam coils, for example, on an average six times that of moving air by fans.

Silencing Equipment.

In cases where noise will be objectionable, such as offices or public halls, special precautions should be taken to avoid transmission of noise through ducts or from the moving machinery to the structure.

The aim should always be to make a system of ventilation as noiseless as possible, though this may not be necessary in industrial work. A good deal can be done by attention to details, but the fundamental factor is to keep low velocity, enabling the fan to be run at slow speed which also saves power. The space required and the initial cost will probably be more than for a system having high velocities, but it cannot be too strongly emphasised that in good class work low air velocities and slow running fans are essential to successful ventilation. Guide vanes should be employed at all changes of section and direction and any obstructions crossing the ducts should be provided with stream-lined casings.

The fan and motor should be insulated from the structure by means of cork or similar material placed between the foundations and the floor upon which this stands. It is also advisable to provide the motor with anti-vibration foundations and to employ a belt drive between the motor and the fan, using endless rubber belts for this purpose. Also the sheet metal connections to the inlet and outlet of the fan should not be bolted direct to the fan casing but should terminate a few inches from the casing, the connection being completed by a sailcloth joint. In special cases where absolute silence is essential it may be found necessary to line parts of the trunks with sound absorbing material. This may also be necessary in cases where a common trunk serves a number of rooms, the trunk connecting the various rooms being similarly lined with acoustic sheets so as to avoid transmission of noise from one room to another. An increase in the section of the trunk to allow for this material must be made so that the air velocity is not increased.

SECTION XXXIV

PART III

LIGHTING.

(Revised by the Lighting Service Bureau.)

Terms in Illumination.

International Candle.—This is the unit of light intensity standardised in Great Britain, the United States of America, and France (*Bougie decimale*), and is one-tenth the intensity of the standard 10 candle Harcourt Pentane lamp burning under specific conditions of barometric pressure and humidity.

The relationship between the International Candle and other units is shown in the following table:

Unit.	Is Equivalent to: International Candle.	Hefner Candle.	Carcel Unit.
One International Candle	1·0	1·11	0·104
One Hefner Candle	0·9	1·0	0·09375
One Carcel Unit	9·6	10·66	1·0

Mean Horizontal Candle Power.—As the intensity of a light source generally varies in all directions, this term is employed to denote the mean candle power obtained by averaging the candle-power readings measured in all directions on a plane passing through the centre of the light source and perpendicular to its axis.

Mean Spherical Candle Power (M.S.C.P.).—This is the mean of the candle powers measured in all directions.

Lumen.—The unit of light flux. It is the amount of light flux contained in a unit solid angle (57·3°) of a sphere with a non-reflecting internal surface which has a uniform light source of one candle situated at the centre. A light source of one mean spherical candle emits 4π (12·57 lumens (see fig. 1).

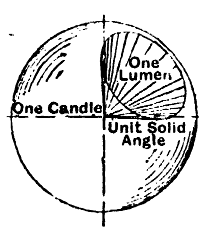

FIG. 1.

Foot Candle or Lumen per Square Foot.—The unit of illumination. If a uniform point source of light of 1 candle intensity in all directions is situated at the centre of a sphere of 1 foot radius, every square foot of the spherical surface will be illuminated to a density of 1 foot candle. Alternatively, it may be said that if one lumen illuminates an area of 1 sq. ft., the average illumination will be 1 foot candle.

Lux or Metre Candle.—The Continental unit of light density is analogous to our foot candle unit. When an area of 1 square metre is illuminated by one lumen, the resultant illumination is 1 lux or metre candle. It follows that 1 foot candle equals 10·76 lux.

Brightness.—The brightness of a surface is the quotient of the luminous intensity in a given direction divided by the area of the surface projected on a plane perpendicular to that direction.

For electric lamps and fittings this quantity is expressed in candles per square inch, while for large surfaces it is usually stated in candles per square foot.

Illumination.

Illumination, or the density of light received by an object, is measured in terms of foot candles, and can be shown to be directly proportional to the candle power and inversely proportional to the square of the distance from the light source, *i.e.* $I = \frac{C.P.}{D^2}$.

If a surface is oblique to the rays, $I = \frac{C.P.}{D^2} \cos\theta$, where θ is the angle subtended between the incident light and normal to the surface.

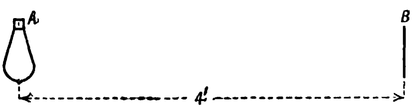

FIG. 2.

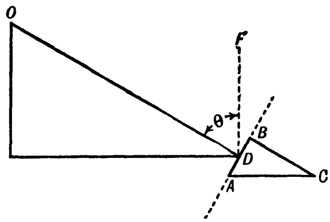

FIG. 3.

Example.—In fig. 2, if A is a lamp (electric or otherwise) giving 16 C.P. in a horizontal direction, the illumination at the point B, 4 ft. away, would be $\frac{16}{4^2} = 1$ foot candle, since the intensity of light varies inversely as the square of the distance. To get the normal illumination at any given point, the candle power in that particular direction must be divided by the square of the distance to the point illuminated. As previously explained, if the surface illuminated is not at right angles to the direction of the light, the value of the illumination obtained, as above, must be multiplied by a reduction factor, taking into account the angle at which the rays strike. A beam of light coming in the direction of OD (fig. 3) falls upon a plane AB, illuminating it with a density of 1 foot candle, then the illumination on the plane AC, which intercepts the same amount of light as AB, would be less as the light is spread over a larger surface, the reduction being in the ratio of AB to AC, which is the cosine of the angle ODF. Thus the effective illumination on any plane at a given point will be:

$$\frac{C.P}{\text{distance}^2} \times \cos\theta$$

where θ is the angle between the direction of the ray and a perpendicular to the plane considered.

NOTE:—The above is only true for a point source of light, *e.g.* a street lamp in an arterial road. In interiors, the physical size of fittings, and the reflection from walls and ceiling modify the law, so that the fall in illumination with distance is less than the amount indicated above.

BRIGHTNESS.

The brightness of an object under a given illumination depends on the amount of light reflected back by its surface, and this depends on the colour and the nature of its finish. The following table gives the approximate percentage of incident gas-filled lamp-light reflected by various coloured paints. Figures for fluorescent light are generally similar.

APPROXIMATE REFLECTING POWER.

	Per Cent.		Per Cent.
Matt White	84	Golden Brown	31
Deep Cream	70	Sea Green	38
Light Buff	61	Sage Green	19
Primrose	70	Sky Blue	47
Orange	36	Turquoise Blue	27
Salmon Pink	42	Light Battleship Grey	44
Post Office Red	21	Dark Battleship Grey	26

Photometry.

As its name implies, photometry deals with the measurement of light. By comparing the unknown light source with a known standard and using the fundamental stated above—that is, that the intensity is inversely proportional to the square of the distance—photometric readings are reduced to the measurement of lengths. In a simple photometer the standard lamp and the light source to be measured are mounted on a horizontal bench with a movable screen placed between them (see fig. 4). The screen is then moved between the lamps until both its sides appear to have the same brightness. The distance AO and BO are then measured and the candle power calculated from the fact that:

$$\frac{\text{OP.A}}{\text{AO}^2} = \frac{\text{OP.B}}{\text{BO}^2} \quad \therefore \text{OP.A} = \text{OP.B} \times \frac{\text{AO}^2}{\text{BO}^2}$$

While making such readings care must be taken that the screen is shielded from any light from other sources.

FIG. 4.

A great difficulty in making candle-power measurements is the difference in the colour of various light sources, and for accurate work special means have to be adopted. One method is to employ a flicker photometer such as the Simmance-Abady Flicker Photometer. This instrument is based on the fact that if a surface is illuminated alternately by two light sources it appears to flicker, due both to variations in light intensity and colour. By varying the speed of the alternations it is found that the eye is more sensitive to variations of intensities than to changes of colour; so by using a critical speed of exposure the surface assumes a neutral tint only affected by flicker due to variations in intensity, and so, under these conditions, the illuminations on the screen can be balanced in the usual way.

In the actual instrument these alterations are obtained by rotating a specially shaped disc between the light sources. The rotor is provided with surfaces that slope alternately to either side, so that at any instant during the rotation the portion in front of the eyepiece is only illuminated by one lamp.

INTEGRATING PHOTOMETER.

The sphere photometer is another form of instrument specially designed for measuring the mean spherical candle power of a light source. The apparatus consists of a large sphere with a whitened mat interior surface; the light source being placed in the centre. It can be shown that every part of the interior surface will receive the same amount of light by repeated reflections—in other words, the light is automatically averaged out; by placing a small window of diffusing glass in the side of the sphere this average intensity can be measured by the usual photometer method.

As mentioned, the effect depends on reflections in the interior, and so the window has to be carefully shielded from direct light from the source of light, also the readings must be multiplied by a constant depending on the nature of the internal surface.

PORTABLE PHOTOMETERS OR 'LIGHTMETERS.'

Although the measurement of candle power is important for certain purposes, we are usually more concerned with the measurement of the actual illumination reaching the working plane. Small portable 'lightmeters' have recently become available for this purpose, working on the photo-electric principle; the light falling on a light-sensitive cell generates current which is passed to a micro-ammeter calibrated in foot candles, no auxiliary apparatus being required.

These lightmeters are generally calibrated to measure illumination from gas-filled lamps, and are reasonably accurate under natural daylight or fluorescent lamp light. Where strongly coloured light is to be measured, however, a correction factor, obtainable from the makers of the instrument, should be used.

The usual range is 0–50 foot candles, while in most instruments a shunt or masking plate may be used to enable readings up to 250 or 500 foot candles to be obtained.

Polar Curves.

Before suitable reflectors can be designed for a given source of light, or in fact before any real idea can be formed as to the characteristics of such a source, it is necessary to know how the light intensity varies in all directions. The polar curve is a very convenient way of showing

these variations, and an example is given in fig. 5. The distance scaled along any line from the centre is proportional to the candle power in that particular direction. When handling light sources, the illuminating engineer needs information as to the nature of the light distribution complete with reflector. This data is recorded in a similar type of graph; and fig. 5 also shows how the light distribution has been completely changed by fitting a reflector; curve A shows the light distribution of a particular lamp alone, while curve B gives its distribution after a reflector has been installed. It will be seen that by means of the data from such polar curves, light can be properly controlled both as regards the design of fittings and installation for specific purposes.

Often it is necessary to compute the total lumens output from a polar curve, or more exactly the mean spherical candle power from which the lumens can be easily calculated. If the light source is symmetrical in its horizontal distribution and not too irregular in its vertical variations, this can be readily performed by taking readings at what are known as the Russell Angles; the mean spherical candle power being the average of such readings. Taking the lower vertical ordinate as our zero, readings should be taken at the following angles:

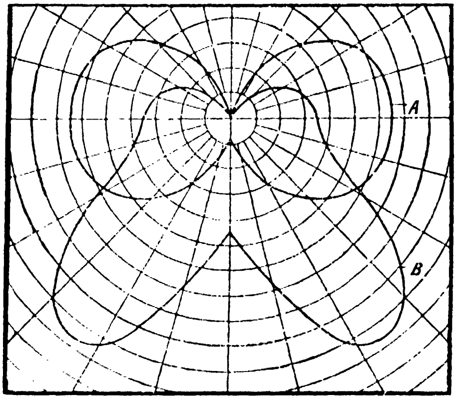

FIG. 5.

Degrees.

25·8	60·0	84·3	107·5	134·4
55·6	72·5	95·7	120·0	154·2

As explained, the M.S.C.P. is the arithmetic mean of the ten readings; while if the lumen output is required this result has simply to be multiplied by 12·57.

Requirements of Good Illumination.

Illumination must be acceptable to the eye. We should be able to see objects clearly and with a minimum of fatigue. To accomplish this result certain conditions must be fulfilled.

(1) There must be sufficient illumination. Since objects are seen by means of the light which they reflect, more light must be thrown on dark objects than on light ones.

(2) Intensely bright lights in the field of vision should be avoided. The iris closes somewhat in order to afford a protection from such lights, and the amount of light received from illuminated objects is thereby so reduced that they cannot be seen clearly. This accounts for the well-known dazzling effects of searchlights and of many headlights. The intrinsic brilliancy or candle-power per square inch of luminous area should therefore be kept as low as possible; it should preferably not be higher than 3, if the source of light is in the field of vision. Clear bulbs should certainly never be used where the filaments are continuously in view. When reflectors are used it is generally desirable to employ some form of obscured lamp.

(3) Flickering lights should be avoided. Poorly regulated circuits, such as those having varying power loads, cause disagreeable flickering. Metal filament lamps have an inherently better regulation than carbon filament lamps, and electric discharge lamps have better regulation than metal filament lamps.

(4) Where colour matching is vitally important special colour matching fittings may have to be employed but for most industrial purposes absolutely correct daylight is not required, and

fluorescent tubular lamps referred to on p. 705, which give a very close approximation to natural daylight, may be employed.

The size of the fittings is a question of design. In deciding upon the proper sizes of lamps to use, one must consider the spacing of present points, if building is already wired, and the position of pillars, beams, etc. In general the fewest fittings consistent with good distribution will be the most economical, as the total cost of wiring, reflectors, and lamps, as well as the maintenance charges, will be reduced, but a greater number of smaller fittings will give less shadow.

In many cases it is preferable entirely to rewire the premises in order to obtain correct illumination.

Illumination Calculations.

During recent years, the 'point-to-point' system referred to in the early part of this section has been generally abandoned in favour of the 'lumen' method of pre-determining the average illumination of an installation. This is essentially due to the fact that, owing to the accumulated experience of illuminating engineers, it has been found possible to take into consideration the contributory effects due to reflection from the ceiling and the walls. The following gives the method of procedure that is adopted generally at the present time :—

Steps in the Design of a Lighting System.

1. *Intensity of Illumination.*

The foot-candle illumination according to good modern practice for different classes of operations are given in Table I., pp. 691–695. In many circumstances, particularly when dealing with dark materials, higher values are desirable.

2. *Type of Lighting Fitting.*

The selection of the lighting fitting depends, not only on the requirements of the work, but in some measure on the construction of the room and the colour of the ceiling and walls. For instance, it would be undesirable to install totally indirect lighting equipment where the ceilings are very dark. The choice of a particular fitting would depend on which of the factors of glare, efficiency, shadow, appearance, etc., are considered of primary importance. A general guide to the characteristics and applications of various types of fittings is given below :—

Characteristics of Lighting Fittings.

Direct (A)—Reflector such as Standard Dispersive and equivalent reflectors for electric discharge lamps.

For industrial interiors where materials worked are not highly polished. Usually mounted at medium heights, it may occasionally be used for high bays where a sideways spread of light is desirable. Direct light from the lamp is cut off at an angle at least 20° below the horizontal. It has a high efficiency and is easy to clean. Maximum illumination is provided on the horizontal plane, fair illumination on the vertical. The appearance of the room is essentially practical, as no light goes directly upwards. Depth of shadow is moderate to hard, depending on the spacing. The reflector may be fitted with a clear or frosted dustproof cover glass, the latter reducing direct and reflected glare.

Direct (B)—Reflector with enclosed diffusing globe such as Industrial Diffusing fitting.

For industrial and other interiors where there is risk of direct or reflected glare. It gives softer shadows and requires slightly more wattage than the Direct (A) type, but (in most examples) allows some light to go upwards to illuminate the ceiling, giving a better appearance to the room.

Direct (C)—Concentrating Reflector.

For high mounting above travelling crane, etc. Most of the light is concentrated into the 0–25° zone from the downward vertical. The cut-off angle is about 30° below the horizontal. A cover glass may be fitted as for the Direct (A) type.

Direct—Laylights and Ceiling Panels.

Suitable for a wide variety of commercial interiors. If the luminous area is of sufficiently low brightness, high quality lighting can be obtained, with very soft shadows and no glare. Where the top is open to admit daylight the efficiency will be lower than when a reflecting top is used. The ceiling tends to be dark unless the laylight or panel projects slightly below the ceiling and translucent side panels are employed, or unless supplementary upward lighting is provided by other means.

Semi-Direct (A)—Enclosed Fittings with major light flux downwards.

This type is generally of good appearance, suitable for 'utility' lighting of unpretentious offices and shops. It has a good efficiency and allows 10 to 40 per cent. of the light to go upwards towards the ceiling. Some examples may be too bright for glossy materials to be viewed comfortably.

Semi-Direct (B)—Suspended luminous beam with diffusing casing.

This type which is generally designed and built to suit the particular interior, can give excellent lighting in all respects. The line of light emphasises the length or width of the room, as desired,

The appearance and efficiency of the fitting very widely according to the constructional details and the materials used. The lighting effect may be ruined by a few dead lamps, therefore maintenance should be frequent and thorough.

General Diffusing—Enclosed diffusing fitting giving approximately equal light output in all directions.

This is generally regarded as an alternative to Semi-Direct (A), with comparable efficiency but greater diffusion, and allowing more light to reach the ceiling. It is suitable also for school classrooms with ceiling height above the average. Shadows are soft and the fitting is easily kept clean. For equal average brightness, the light output in a particular direction is proportional to the projected area; therefore flat or vertical cylindrical shapes tend to give most light in the up-and-down or sideways direction respectively.

Semi-Indirect.—Fitting giving the major part of the light in an upward direction.

This usually has a very good appearance, and is suitable for offices, reception rooms, and shops where prestige is important: also for schools. It needs a greater wattage than the more direct types, but gives very little shadow or likelihood of glare. If of the open type, it requires frequent cleaning to maintain efficiency. A light-coloured ceiling is essential.

Indirect (A).—Indirect Fitting and Indirect Trough.

Suitable for providing moderately high intensities in commercial interiors without glare and with practically no shadow, but tending to give dull and monotonous lighting at low and medium illumination levels unless supplementary lighting provides bright areas to relieve the effect. This type requires relatively high wattage and frequent cleaning. The fitting or trough appears as a dark patch against the lighted ceiling unless it is designed to allow leakage of light to exterior surfaces. A very light colour of ceiling and upper walls is essential.

Indirect (B).—Indirect Cornice.

This type is particularly useful when the ceiling is required to be kept clear, *e.g.* to show ornamentation. It should not be used alone in rooms of great width in comparison to height, as sufficient light will not reach the centre part of the ceiling. The character of the lighting will be similar to the Indirect (A) type, but the efficiency varies widely with the structural details. A very light colour of ceiling and upper walls is essential.

3. *Location of Fitting.*

Tables II (*a*) and II (*b*) show the maximum desirable spacing of fittings, according to the permissible mounting height. When these or less spacings are used, reasonably uniform illumination will result.

4. *Size of Lamp.*

After the position of the fittings has been settled on the plan according to the space available the size of the lamp can be determined by consideration of the following factors:—

(*a*) *The Room Index.*—In a large room the lighting system has a higher efficiency than in a small room, owing to the fact that a number of fittings contribute directly to the amount of light that reaches the working plane, without loss due to absorption of light by walls, etc. The room index should be obtained from Table III, p. 698, taking into account the proposed mounting height of the fitting. Note that the fitting hangs down at least 1 ft. from the ceiling, and that the working plane is some distance above the floor.

(*b*) *Maintenance Factor.*—Allowance has to be made for the depreciation of lighting efficiency due to a normal deposit of dust and dirt on the lamps, fittings, walls and ceiling. Special circumstances may require a higher or lower allowance, but generally the illumination is assumed to fall by 20 per cent. due to these causes, when the installation is in service. Thus the initial illumination should be 25 per cent. higher than that required in service.

Note.—The decrease in lamp efficiency during life is catered for by using the 'average throughout life' lumen output figures shown in Tables V to VIII, p. 704.

(*c*) *Coefficient of Utilisation.*—On p. 701, Table IV, coefficients of utilisation are given for a particular fitting. Having chosen the fitting and obtained the value of the Room Index from Table III, the corresponding coefficient of utilisation, according to the nature of the walls and ceiling, can readily be obtained direct or by interpolation. This figure represents the percentage of the lumens generated by the lamp that reach the plane of work. Note that all windows, skylights, etc., should be treated as dark surfaces, unless covered by light-coloured blinds, as they permit light from the fittings to pass through and thus become lost.

$$\left.\begin{array}{c}\textbf{Lamp Lumens required}\\ \textbf{per sq. ft.}\end{array}\right\} = \frac{\text{Foot-candles}}{\text{Coefficient of utilisation} \times \text{maintenance factor}}$$

Area in sq. ft. per fitting = Transverse × longitudinal spacing (sq. ft.)

$$\left.\begin{array}{c}\textbf{Lamp Lumens required}\\ \textbf{per unit.}\end{array}\right\} = \textbf{(Area in sq. ft. per fitting)} \times \textbf{(Lamp lumens required per sq. ft.)}.$$

Having thus determined the lamp lumens required per point, the wattage of the lamp to be used can be obtained by reference to Tables V to VIII, pp. 704–706.

ILLUMINATION DESIGN FOR A MULTI-STORY MACHINE SHOP FOR ROUGH WORK.

Room is 65 ft. long and 39 ft. wide, with 13 ft. ceiling. Beams divide the ceiling naturally into 13 ft. by 13 ft. sections. Ceilings and walls painted white. Height of plane of reference 3 ft. above floor. Supply voltage 230 volts.

Summary of Steps in the Design.	Reference.	Required Data
1. Foot-candles recommended	Table I	10
2. Type of fitting used	Page 2233.	Direct (A).
3. Spacing and mounting height		
Possible mounting height above work	Depends upon ceiling height	9 ft.
Maximum spacing permissible	Table II (a), page 2241.	13½ ft.
Actual spacing to suit interior	Symmetrical with respect to bays	13 ft.
Actual mounting height above work	Table II (a), page 2241.	9 ft.
Height above floor	—	12 ft.
4. Size of Lamp		
Room index	Table III, page 2243.	F
Coefficient of utilisation	Table IV, page 2244.	0·53
Maintenance factor	—	0·8
Lamp lumens required per point	Formulæ	4000
Lamp size	Table V, page 2245.	300 watt.

Illumination Values.

The values given below are service values of average illumination. Designs planned in accordance with this book will give initially 25 per cent. more light due to the maintenance factor of 0·8.

The recommendations include most of the headings in the Table of Recommended Values of Illumination, published by the Illuminating Engineering Society and are in line with good modern lighting practice.

TABLE I.—RECOMMENDED AVERAGE SERVICE VALUE OF ILLUMINATION.

COMMERCIAL AND PUBLIC BUILDINGS.

Description.	Foot-candles	
ART STUDIO		Special lighting
AUTOMOBILE SHOW ROOM		Special lighting
CHURCH:		
Church	7	
Church Hall	7	
CINEMA		Special lighting

Room Indices printed in Italics.—In certain instances where normal spacing indicates the use of one, or at the most two fittings, the average illumination (obtained by the lumen method of design) may not be a good indication of the usefulness of the lighting owing to the comparatively large variation of intensity at different points on the working plane. In such instances it is preferable to use the point-by-point method of design when direct or semi-direct fittings are to be employed.

This also applies to general diffusing fittings in rooms with dark decorations, but not to fittings giving a greater proportion of upward light.

In rooms more than 115 ft. wide, the Coefficient of Utilisation will continue to increase gradually, and in the case of a Direct lighting installation will eventually equal the Luminous Efficiency of the fitting (Column 2 of Table IV) in rooms of infinite size.

TABLE IV.—COEFFICIENT OF UTILISATION.

COVER GLASSES

When a front cover of glass is fitted to reduce the brightness of any of the above reflectors, or to exclude dirt, an additional allowance must be made for light absorption, depending on the shape, type and quality of glass used, the last being especially critical with reflectors for discharge lamps. As a general guide, the above figures should be multiplied by 0·7 for flashed opal, 0·75 for frosted, and 0·9 for clear glasses, but it is strongly recommended that definite figures be obtained from the manufacturers of the equipment in question.

* *Multi-lamp fittings.*—In general, fittings housing 2 and 3 lamps will have a Coefficient of Utilisation approximately 0·9 and 0·85 of the above figures respectively.

Electric Discharge Lamps.

One of the latest developments in the manufacture of electric lamps is the introduction of the high pressure mercury vapour electric discharge lamp, which has no filament, as in the ordinary gas-filled lamp, but gives light by means of an electric discharge in an inner tube surrounded by an outer jacket. These lamps give about 2½ times as much light as the same size of filament lamp, and are therefore highly economical in those situations where their particular colour characteristics are desirable or not a disadvantage.

The spectrum of these lamps is not continuous, being a line spectrum composed of green, yellow, some blue, and a little red. The light appears to be greeny-blue, and is particularly suited for all inspection purposes (except those involving discrimination of red colours) since scratches, cracks and other flaws show up much better than under the light of filament lamps. Stroboscopic effects are usually negligible except in the case of very high speed machinery, and they can then be

mitigated by connecting adjacent lamps to different phases of supply. The penetrating and resolving power of the light from these lamps, combined with their low running cost, has resulted in rendering any local lighting unnecessary in many situations, such as foundries, machine shops, stores, etc.

One type of mercury lamp is fitted with a fluorescent outer bulb, which adds some orange-red light and thus slightly improves the colour-rendering properties of the lamp. This modification is effected with little loss of efficiency, and allows some industrial operations to be carried out which could not be done under ordinary mercury lamps.

In another type a good colour of light is obtained by combining a mercury discharge and a tungsten filament in the same outer bulb. The filament exerts the necessary control over the current, and auxiliary apparatus is therefore not required.

Sodium Lamps.

Sodium vapour electric discharge lamps are also used to a considerable extent where their monochromatic yellow light is suitable, particularly in factories, streets and for flood-lighting. Nominal lumen ratings of these lamps are shown below.

TABLE VII.—NOMINAL LUMEN RATINGS, ETC., OF SODIUM VAPOUR ELECTRIC DISCHARGE LAMPS.

Watts.	Average Lumens throughout Life.	Cap.

60	3,420	B.C.
85	5,350	B.C.
140	8,960	B.C.

Tubular Fluorescent Lamps.

In these lamps almost the entire light output is obtained from the fluorescence of a powder deposited on the inner surface of the tube, in which a discharge takes place through a low pressure of mercury vapour.

Three colours of light are available. (1) *Daylight*, giving a light apparently similar to natural daylight in general, though weak in deep red light which makes colour rendering of red tones rather unsatisfactory. (2) *Warm White*, giving a pinker light than the above, sometimes preferred for applications where the lighting is required to be restful and decorative. This type has the same efficiency as the Daylight. (3) *Natural*, in which a better balance of colours than in the other two types is obtained, though with a slight reduction of efficiency. This type renders colours in general more truly and, though only recently introduced, is likely to become the most widely used.

The total heat generated by fluorescent lamps is about one-third of that generated by filament lamps giving equal light output, and the radiated heat about one-fifth as much. The surface brightness of the lamps is low, and glare is thus reduced to a minimum, though it is usually still desirable to screen the lamps and/or ensure that the background against which they are seen is not dark, particularly at high illumination levels.

In common with all other discharge lamps the fluorescent lamp must be connected in series with a current-limiting device (choke) and in addition special arrangements are necessary for starting, since the electrodes require to be pre-heated before the discharge takes place. This is usually effected by a starter switch which allows current to pass through the electrodes for a few moments, and then automatically breaks the circuit, inducing in the choke a voltage surge which starts the lamp. Starters are of two types, thermal and glow, and in modern installations either may be used without alteration to the circuit.

An alternative device, available at the time of writing (December 1948), for the 80-watt lamp only, is an instant (or quick) -start unit. This is a high reactance auto-transformer connected across the lamp, with a low-voltage winding connected to each electrode. When switched on, the discharge will strike automatically as soon as the electrodes reach operating temperature (*i.e.* in a fraction of a second). This arrangement requires the usual series choke to be retained, and an earthed metal strip must make contact with the lamp exterior along its whole length.

Lamps more than 2 ft. in length require one set of control gear each. Lamps of 2 ft. length and less may be run two in series with a single choke on 200/250 volt mains ; in this case lamps must be of the same wattage rating.

TABLE VIII.—NOMINAL LUMEN RATINGS, ETC., OF TUBULAR FLUORESCENT LAMPS.

Installation Details.—When used for general lighting at heights greater than 4 ft. 6 ins. above the working plane, enamelled trough reflectors for fluorescent lamps perform in a similar manner to Direct (A) reflectors for gas-filled lamps, so far as distribution of light and efficiency is concerned, and the coefficient of utilisation for Direct (A) fittings may therefore be used.

Since there is an appreciable drop in light output from fluorescent lamps during the first 150/200 hours of life, the initial efficiency of the lamp should be ignored for design purposes.

* With two lamps in series on 200/250 volts.
† Elongated type choke. For block type the loss is approximately 10 watts.
‡ Including standard bi-pin holders.

Instead, the 'average lumens throughout life' should be taken as the output, and a maintenance factor (usually 0·8) should be applied, as for any other class of lamp.

Lamp life will in general be about three times that of gas-filled lamps, but is dependent to some extent on the frequency of switching. With the lamps kept burning for prolonged periods the life may be longer, or shorter when they are only used for brief periods.

Tubular fluorescent lamps lend themselves particularly well to localised lighting of particular areas such as lines of machines or benches. The average illumination to be expected in service from an 80-watt lamp may be gauged from the tables below. (Deduct 10 per cent. for Natura colour lamps):—

SINGLE FITTING—AREA OVER WHICH DIVERSITY OF ILLUMINATION DOES NOT EXCEED 2 : 1.

Height above Working Plane.	Approximate Area.	Foot-Candles. Max.	Min.	Mean.
2 ft.	Ellipse 5 ft. × 3 ft.	90	45	70
3 ft.	Ellipse 6 ft. × 5 ft.	45	25	35
4 ft.	Circle 6 ft. × 6 ft.	30	15	22
5 ft.	Circle 7 ft. × 7 ft.	20	10	15

SINGLE ROW OF FITTINGS—ILLUMINATION VALUES ON A BENCH 4 FT. WIDE

Height above Working Plane.	Spacing (Centres).	Foot-Candles. Max.	Min.	Mean.	Distance between Rows.*
3 ft.	6 ft.	54	24	40	12 ft.
4 ft.	6 ft.	36	24	30	14 ft.
4 ft.	8 ft.	32	18	25	13 ft.
5 ft.	6 ft.	26	22	24	15 ft.
5 ft.	8 ft.	22	16	20	14 ft.
5 ft.	10 ft.	20	12	16	13 ft.

A continuous line of single-lamp 80-watt fittings mounted centrally 2 ft. above a bench 2 ft. wide will give an average illumination of the order of 80 foot-candles.

Architectural Lighting.

Except where artificial light is used purely for utilitarian purposes, the modern tendency is to spread the light over large surfaces instead of using small, brilliant light sources. This effect is commonly achieved by fitting the lamps behind sheets of opal or otherwise obscured glass, the whole fitting being built-in to the existing structure. In order to obtain an even lighting effect over the whole surface of the glass, the lamp spacing—distance behind glass ratio for pearl lamps and various types of glass should be as shown in the table below. With tubular fluorescent lamps the spacing may be approximately 50 per cent. greater.

LAMP SPACING IN INCHES.

Glass.	D = 4	6	8	10	12
Frosted stippolyte .	2½	3	3½	4½	5
Acid etched .	2	3	4	5	6½
Flashed opal . .	5	7	9	11½	13½

D = Distance of lamp centres behind glass.

*** *Note.*—This column gives the maximum distance apart at which it is safe to mount rows of fittings, in order to comply with the statutory minimum requirements of 6 foot-candles in working areas. If this distance is exceeded it may be necessary to install additional general lighting.**

Street Lighting.

Modern street lighting practice is based on the recommendations contained in the Report issued by the Ministry of Transport Departmental Committee on Street Lighting in 1937. This aims, in general, at providing an evenly bright road surface against which obstructions are seen as dark objects in silhouette. Provision of even road brightness does not necessarily require even illumination, in fact, the variation of illumination from point to point may be very wide.

The siting of street lighting posts is perhaps more important than any other consideration. A lantern will provide a T-shaped patch of brightness on a part of the road surface situated between the lantern post and the observer, and the aim is generally to locate the posts in such a position relative to each other that the individual bright patches merge to form a uniformly bright field. Special care is required to ensure that entry to and exit from roundabouts, crossings and junctions are clearly visible whatever the direction of movement; on bends lanterns are generally located on the outside of the bend and closely spaced.

The fuel shortage has emphasised the advantages of discharge lamps for non-residential roads, and most new or improved installations for such locations use either mercury or sodium discharge lamps. Recently a considerable amount of tubular fluorescent lighting has also been installed in the civic centres or main shopping streets of towns, and it is already clear that this type of lighting will be used to an increasing extent in future. Partly on account of the limited light output obtained from the largest fluorescent lamp (80 watts) multi-lamp lanterns are generally used on a fairly close spacing, resulting in comparatively high capital costs; but the pleasant and comfortable nature of the light obtained is often considered to justify its use in the situations mentioned. In addition, the use of multi-lamp lanterns permits some lamps in each lantern to be extinguished at, say, midnight for purposes of economy without upsetting the distribution of light on the road surface.

SECTION XXXIV

PART IV

FIRE EXTINCTION AND PREVENTION.

(Contributed by Hubert B. Graham, M.I.Mech.E.)

First-Aid Precautions.

First-aid fire precautions include the provision of portable extincteurs, stirrup pumps, water in buckets, sand in bins and bicarbonate of soda and dry sand in sealed containers. The three last named are suitable for use only in cases of very small fires on bench or floor.

A standard Stirrup Pump (BS/ARP 33) is capable of dealing with fires at a higher level and of a more serious character. It requires a team of three persons, however, to maintain it in operation for the discharge of water at the rate of 1½ gallons per minute, to a distance of 25 ft.

The comparative performance of a portable extincteur expelling water, or an alkaline solution dilute, operated by one person only, is 2 gallons per minute, thus, with a team of three persons operating three extincteurs, the rate of discharge would be 4 times that of a stirrup pump, which render portable extincteurs the most effective first-aid means of extinguishing carbonaceous fires.

For *special* fire risks, different types of portable extincteurs are available and mention of these is made hereunder.

PORTABLE FIRE EXTINCTEURS.

The British Standards Institution (B.S.I.) has defined a portable fire extinguisher (alt. extincteur) as a first-aid fire appliance that can be carried by hand.

B.S.I. Specifications (ref. BS) have been issued for different types of extincteurs designed to deal with different fire risks, namely :—

(i) BS 138/1922	Water and carbon dioxide (CO_2).
(ii) BS 138/1935	Acid alkali (alt. soda-acid).
(iii) BS 740/1937, Part 1 . . .	Foaming solution.
(iv) BS 740/1937, Part 2 . . .	Carbon tetrachloride ($C.Cl_4$).

Other types for which B.S.I. Specifications have not yet been issued are :—

(v) Methyl bromide (CH_3Br) and nitrogen.
(vi) Carbon dioxide (CO_2) direct gas jet.*
(vii) Carbon dioxide (CO_2) and bicarbonate of soda.*

The specifications for extincteurs (i), (ii), (iii) and (iv) detail the essential requirements according to British practice. They were drafted in consultation with the Admiralty, War Office, Air Ministry, Home Office and Ministry of Works and Buildings, and subsequently adopted by these Government Departments in place of departmental specifications formerly issued.

The Fire Offices Committee (F.O.C.) also assisted in the drafting of these specifications and subsequently adopted them in place of earlier F.O.C. Specifications. Strict compliance with F.O.C. Rules and Regulations is essential in the equipment of industrial buildings in order to qualify them for rebates of premiums on (Tariff) Fire Insurance Policies.

Other bodies represented on the B.S. Committee included the National Fire Brigades Association, Professional Fire Brigades Association, Institution of Fire Engineers, Institution of Chemical Engineers, Institution of Mechanical Engineers, Institution of Gas Engineers, Iron and Steel Institute, Association of British Chemical Manufacturers and the Fire Extinguisher Trades Association.

---

* For the composition, strength and test-pressure of CO_2 steel cylinders used for (vi) and (vii), see BS 401/1931-37-38.

The Board of Trade reserves the right to approve extincteurs proposed for installation on marine passenger carrying vessels.

The essential requirements to be noted in the aforesaid specifications are :—regulation markings, standard tests, capacity and expansion space, safe-load indicator, nature of dynamic or chemical charge, method of actuation, velocity and throw of jet, materials, dimensions and construction.

The regulation markings to be indelibly printed or etched on the exterior of a liquid type extincteur operated by gas or air pressure in which the working pressure *exceeds* 50 lbs. per sq. in. are : (*a*) A declaration that it has been 'tested to 350 lbs. per sq in.' implying that it has been tested by internal hydraulic pressure to 350 lbs. per sq. in. for a continuous period of 2½ minutes without leakage or visible distortion. (*b*) Its liquid discharge capacity in gallons. (*c*) The year of its manufacture ; and (*d*) the name and address of its manufacturer or responsible vendor. The markings of a liquid type extincteur operated by gas or air in which the working pressure does *not* exceed 50 lbs. per sq. in. shall be as (*b*), (*c*) and (*d*).

The capacity of types (i) and (ii) shall not be less than 1 gallon or more than 3 gallons, type (iii) shall not be less than 1 gallon or more than 2 gallons, type (iv) shall not be less than 1½ pints or more than 2 gallons.

The expansion space in a gas pressure type liquid extincteur shall be such that when fully charged with liquid at a temperature of 100° F., the outlets of the liquid container temporarily closed and the relative maximum gas charge exerting pressure therein, such pressure shall not exceed 200 lbs. per sq. in. in extincteurs in which the working pressure *exceeds* 50 lbs. per sq. in. or shall *not* exceed 100 lbs. per sq. in. in extincteurs in which the working pressure does *not* exceed 50 lbs. per sq. in. On all such extincteurs refillable by an operator after use, the safe-load (*i.e.* liquid filling level) shall be indicated on the exterior of the liquid container.

In the seven types named there are fundamental differences in their effect on different classes of fires resulting from differences in the extinguishing media and differences in the dynamic or chemical charges, but different methods adopted for actuating a given type, as, for instance, type (ii), do not affect the working efficiency of that type but only the manner of operating it.

Type (i) water and CO_2 extincteur discharges chilled water at high pressure exerted by the expansion of CO_2 from liquefied formation to atmospheric formation on release from a small disc-sealed cylinder (alt. cartridge or capsule). In an extincteur of this type of 2 gallons capacity, the dynamic charge is 65 grammes of liquefied CO_2, which, having been compressed to 60 atmospheres in a cartridge, 9 ins. × 1 in. o/d, 73 c.c. content, will, on release, expand to 33·850 c.c. at atmsopheric formation at 15° C., *i.e.* 450 times its original volume when liquefied and equal to 2¾ times the capacity of the water container in which the expansion occurs. Hence the evaporative chilling effect on the water and its high velocity on discharge.

This type is actuated by striking a knob on the headcap, the knob being connected to a piercing pin which punctures the copper sealing disc of the CO_2 cartridge.

Type (ii) acid alkali extincteurs discharge a dilute alkaline solution resulting from the chemical action of an acid in conjunction with a carbonate and/or bi-carbonate solution. The proportion of acid to alkali in the chemical charge varies to some extent in the charges for different makes of extincteurs, but a standard recognised for a 2 gallon capacity extincteur is 2½ liquid ounces of sulphuric acid (sp. gr. 1·84) to 1 lb. 2 oz. of bi-carbonate of soda.

This type may be operated (*a*) by breaking an hermetically sealed bottle containing an acid and thereby allowing the acid to come into contact with the carbonate or bi-carbonate solution, or (*b*) by turning over the extincteur or the acid bottle therein and thereby spilling acid into the carbonate or bi-carbonate solution. The operation (*a*) may be performed by striking a knob on the extinguisher or by a blow on its side.

This type, while generally known as a chemical extincteur, is so only in the sense of producing by chemical reaction the pressure required to expel its liquid content—not that the chemicals employed for that purpose have any virtue as fire extinguishing media, for in a properly proportioned charge the reaction of the alkali to the acid neutralises the latter and renders the former a weak dilute.

The effect of types (i) and (ii) discharged on materials in combustion is (*a*) to cool them so that inflammable gases given off by disintegration may be arrested, (*b*) to damp them so that vapour may arise to assist their extinguishment, and (*c*) by a forcible jet of water or dilute alkaline solution to beat off flames repeatedly until they no longer re-light.

Types (iii) to (vii) extincteurs act on a different principle. They have no appreciable cooling or damping effect nor do they rely on a forcible jet but on fires on inflammable liquids and of electrical origin, they smother combustion by the exclusion of oxygen therefrom.

Type (iii) foam extincteurs discharge a closely knit stream of adhesive bubbles of gas formed by chemical action of an acid salt, stored in an inner receptacle, in conjunction with a carbonate or bi-carbonate solution in combination with a stabiliser, stored in the outer container of the extincteur. Until the year 1942 it had been common practice to place a solution of sulphate of aluminium in the inner receptacle and in the outer container a solution of sodium bicarbonate, saponin and an extract of vegetable syrup. The two latter act as a stabiliser, the function of which is to affect the surface tension of the bubbles of gas resulting from the conjunction of the two solutions so as to provide a tough adhesive wall structure for each bubble thereby permitting

expansion of the gas therein to its normal limit at any temperature without causing the bubbles to burst as they otherwise would do.

The expansion of these bubbles creates a pressure in the extincteur whereby a stream of them is propelled therefrom a distance of upwards of 20 feet in a specified period of time, which, in the case of a 1-gallon extincteur, is from 30 to 90 seconds, according to the climatic condition then prevailing.

The average rate of expansion of the solution with foam is 8 to 1 at a temperature of 50° F. These extincteurs should not be exposed to frost and preferably placed where the temperature does not fall below 50° F.

In 1942, as a measure to limit imports during a state of war, the B.O.T. directed the F.E.T.A. and Central Research Laboratory to combine in research for a substitute for the stabiliser hitherto used as aforementioned. A successful issue resulted in the summer of 1942, but the constitution of this new product is not yet to be divulged.

This type extincteur may be actuated by conjoining the inner and outer solutions in one of the following ways: (*a*) by turning over (upside down) the extincteur; (*b*) by unlocking or piercing a sealing device and turning over the extincteur; or (*c*) by turning over the extincteur or otherwise causing an hermetically sealed bottle containing the inner solution to be broken.

Type (iv) carbon tetrachloride extincteurs. The $C.Cl_4$ used in these should conform to BS. 575/34. It shall be clear, colourless and free from undissolved water and other visible impurities, Sp. Gr. 1·600–1·608 at 15·50° C. and 1·596–1·604 at 20° C.

The $C.Cl_4$ is propelled from extincteurs by one of four methods: (*a*) by means of a direct-acting self-contained hand force pump operated by outward and inward strokes of the plunger by manual effort not exceeding 25 lbs. pull or thrust; (*b*) by expansion of liquefied CO_2 or compressed nitrogen from a small sealed cylinder attached to the extincteur and operated by suitable mechanical means thereby causing the seal of the cylinder to be pierced and liquefied CO_2 or compressed nitrogen to be released into the $C.Cl_4$ container; (*c*) by pressure of compressed CO_2 or nitrogen stored in the $C.Cl_4$ container and operated by suitable mechanical means thereby puncturing the seal of the $C.Cl_4$ container and releasing its contents; (*d*) by pressure of air compressed into the $C.Cl_4$ container at the time the extincteur is operated by means of a hand air pump forming an integral part of the extincteur.

The minimum length of jet of $C.Cl_4$ propelled by any one of these extincteurs shall be 25 feet, and the minimum and maximum rates of discharge for pumps (*a*) and (*d*) shall be 1½ pints in 40–60 seconds for the smallest size; 1 gallon in 60–90 seconds for the largest size, and *pro rata* for intermediate sizes, while for pressure extincteurs (*b*) and (*c*) it shall be 1 quart in 60–80 seconds for the smallest size; 1 gallon in 40–90 seconds for the largest size, and *pro rata* for intermediate sizes.

Type (v) methyl bromide is a stable, colourless and volatile liquid with a boiling point of 4·5° C. which, being stored in a sealed container with added nitrogen to increase the pressure to 50–100 lbs. per sq. in. will, upon release, evaporate rapidly to a vapour of 3·27 times heavier than air at N.T.P. While no B.S.I. Specification has yet been issued for appliances charged with this product, an Air Ministry specification applies to such extincteurs for use on service aircraft and petrol-driven sea-craft.

Type (vi) carbon dioxide extincteurs consist of a standard CO_2 cylinder (BS. 401/31–38) with a CO_2 capacity of 2, 4, 7 or 15 pounds, fitted with a syphon tube, large valve opening, quick opening valve, non-freezing nozzle and conical entrainment shield to limit the amount of air entrained by the CO_2 at the point of discharge. They are charged with liquefied CO_2, which on rapid release emerges a mixture of CO_2 gas and CO_2 snow, particularly effective in dealing with electrical hazards and inflammable liquids.

Type (vii) CO_2 and carbonates appliances consist of a conical powder-container with a standard CO_2 cylinder attached thereto. They are made in two sizes, the smaller one having a carbonates capacity of 288 cub. in. and CO_2 capacity of 288 c.c., the larger ones having double those capacities. To operate the extincteurs they are inverted and the CO_2 released by a trigger valve into the carbonates-container. The CO_2 then emerges at high pressure from a conical nozzle with spreading baffle drawing with it the carbonates on the ejector principle and propelling them to the seat of combustion on which they settle and are converted into added CO_2. The combined discharge is di-electric at 120,000 volts.

Mobile Secondary-Aid Appliances.

In this group are larger models of some of the appliances before described, mounted on wheels, including water corridor pumps, maximum capacity 20 gallons, delivery 10 gallons per minute, effective range 45 ft.; and water and CO_2 pressure engines, maximum capacity 40 gallons, delivery 20 gallons per minute, effective range 60 ft.; also acid-alkali type and foam type chemical engines, ranging usually from 5 to 34 gallons, with range and rate of delivery according to size of nozzle specified.

Major Appliances.

Trailer Pumps have been extensively installed in industrial works during the past five years. The sizes usually employed for this purpose range from a 120/180 g.p.m. light type with pump

detachable from chassis, to a 350/500 g.p.m. heavier chassis type. Normal output of the former 150 g.p.m. at 100 lbs. sq. in.; single jet 130/90 ft. high, and of the latter 430 g.p.m. at 100 lbs. sq. in. single jet 140 × 110 ft. high, suction lift of former 10 ft. and of latter up to 25 ft. Multiple jets reduce length and height of throw, for instance, a single jet of 130 × 110 ft. as above to approximately 110 × 80 ft. double jet.

Colliery fire and rescue stations throughout Great Britain and many engineering, chemical and other industrial works are provided with complete modern fire brigade equipment as specified by the Home Office for the National Fire Service.

Modern petrol motor fire engines range in pumping capacity from 700–900 gallons per minute, 120 b.h.p. weight about 5½ tons to 300–500 gallons per minute, 60 b.h.p. weight about 3½ tons, both working up to pressures of 200 lb. per sq. in. The pumps employed are of two types, multi-stage turbine and reciprocating, the former being provided with a priming device to 'lift' the water when the pump is not coupled direct to a pressure main. Many of these engines (usually described as dual-purpose or D.-P. appliances) carry wheeled escapes which are removable for use separately in case of necessity.

The brigades of large cities are rapidly acquiring mobile turntable-ladders (alt. T.T. appliances), viz. telescopic revolving ladders extending to heights up to 100 ft., the operating mechanism being driven by the petrol motor that propels the machine. These appliances are primarily designed to enable fires in high buildings to be attacked from above but they are also used for life-saving.

The most modern T.T. are in four sections, made entirely of steel. Some are fitted with pumps.

FIXED INSTALLATIONS.

In this group are included hydrant installations. Sluice valve type, or screw-down type or ball type and unions according to local practice. Automatic sprinkler and drencher systems (wet or dry) usually with dual water supply, viz. town water main (with booster pump) and overhead emergency water tank; continuous foam generating plants; pipe installations for reception of water or foam from fire brigade motor pump; static water and CO_2 pressure tanks with pipe line and hose to special points of danger; batteries of CO_2 cylinders or CH_2Br. cylinders (automatically operated by a thermostat or electricon smoke detector) and emulsion-forming water-jet apparatus. To determine the most efficient of these systems for installation in any given circumstances is a matter for reference to the F.O.C. and/or study of reports issued by technical institutions as, for instance, E.R.A. Report V/T.8–1940.

Fire Hose.

The hose generally used by fire brigades is of 2½-in. and 2¾-in. internal diameter. It is woven from flax line and the average grades are suitable for working pressures not exceeding 130 lbs. per sq. in.

The London Fire Brigade uses 2¾-in. diameter rubber-lined flax hose. This has a much lower frictional loss as compared with unlined hose mentioned above, and also the waste of water by porosity leakage is prevented by the rubber lining. The maximum working pressure is 150 lbs. per sq. in.

The loss of head due to friction in delivering 100 gallons per minute through each 100-ft. length of hose is as follows:—

Size of hose.	*Head lost in friction.*
2½-in. unlined	20 ft.
2¾-in. unlined	13 ft.
2¾-in. rubber-lined	5 ft.

Thus, with ten (100-ft.) lengths of hose or 1,000 ft., the friction loss amounts to 200, 130 and 50 ft., respectively. Assuming the head available at the pump to be 300 ft., or 130 lbs. per sq. in., there would be 100 ft., 170 ft. and 250 ft., respectively, available at the jet, which is equivalent to pressures of 31 lbs., 73 lbs. and 107 lbs. per sq. in.

The maximum lengths of hose at which an efficient ¾-in. jet can be obtained with a nozzle pressure of 50 lbs. per sq. in. are as follows:—

Size of hose.	*No. of 100-ft. lengths.*
2½-in. unlined	9
2¾-in. unlined	14
2¾-in. rubber-lined	37

The above figures indicate the advantage of using hose of a larger diameter and the great advantage of rubber lining.

If it be necessary to pump larger quantities of water over longer distances twin lines of hose should be laid out and several pumps arranged in relay or series working.

BRITISH STANDARD FIRE HOSE COUPLINGS.
(No. 336—1936.)

The specification gives the dimensional particulars for three types of couplings—the V-thread, the round thread, and the Morris instantaneous type. The sizes of the two former are 2¼ ins., 2½ ins., and 2¾ ins., and for the latter 2½ ins. and 2¾ ins. diameter with interchangeability.

The following table will be found useful :—

Fire Streams.

Table showing Pressure required at Nozzle and at Pump, with Quantity and Pressure necessary to Throw Good Effective Streams various Distances through Different Size Nozzles, using 100 Feet of Ordinary $2\frac{1}{2}$-inch Rubber-lined Hose and Smooth Nozzles.

Size of Nozzle, $\frac{3}{4}$ inch.							
Pressure at nozzle, in lbs. per sq. in.	40	50	60	70	80	90	100
Pressure at pump, „ „ „	46	57	68	80	91	102	114

Size of Nozzle, $1\frac{1}{4}$ inches.							
Pressure at nozzle, in lbs. per sq. in.	40	50	60	70	80	90	100
Pressure at pump, „ „ „	84	106	127	148	169	190	211
Imperial gallons per minute . .	246	275	301	325	348	368	388
Distance thrown horizontal, in ft.	63	70	76	81	85	90	93
Distance thrown vertical, in ft. .	67	77	85	91	95	99	101
Size of Nozzle, $1\frac{3}{8}$ inches.							
Pressure at nozzle, in lbs. per sq. in.	40	50	60	70	80	90	100
Pressure at pump, „ „ „	107	134	160	187	214	240	268
Imperial gallons per minute . .	301	337	369	398	426	452	476
Distance thrown horizontal, in ft.	66	73	79	84	88	92	96
Distance thrown vertical, in ft. .	69	79	87	92	97	100	103

N.B.—The above pressures are based on the supposition that the hose is coupled direct to the delivery of the pump and while the stream is flowing; if, however, the hose is coupled to a hydrant which is supplied direct from the pump, then the corresponding fire pump pressure must be greater than the hydrant pressure by an amount equal to friction loss and difference of head between hydrant and pump.

The pressures given in the table are *indicated* pressures, not effective pressures; effective pressures would be slightly greater.

The distances given are for *effective* fire *streams* adapted for fire purposes, and are not for mere isolated drops. (*Freeman.*)

FIRE STREAMS AND ELECTRIC CIRCUITS.

It has always been believed to be dangerous to those handling a hose to allow the stream to come in contact with an electric circuit. Prof. F. C. Caldwell has found by experiment that there is no danger of shocks when the distance between the nozzle and circuit is more than 25 ft., irrespective of the voltage. ('*Power.*')

Fire-Resisting Buildings.

The following is a reasonable standard for these :—

(1) Walls should be of hard burnt brick or cement concrete (composed of cement and an aggregate of sand, gravel, broken brick, burnt ballast or the like; a coke breeze aggregate should be avoided). External or party walls of brickwork should be at least 8½ ins. in thickness. External walls constructed of reinforced concrete should be not less than 4 ins. in thickness in the panels, and party walls of reinforced concrete should not be less than 8 ins. in thickness.

(2) Walls built as described above and containing no openings are of great value in checking the spread of fire.

(3) Stone walls have not been found to resist action of fire and water so satisfactorily as brick or concrete.

(4) (*a*) In all cases roofs should be covered externally with fire-resisting material.

(*b*) Roofs should be constructed as strongly as possible of incombustible material and, if glazing is necessary, glass should be not less than ¼ in. in thickness in direct combination with metal, the melting point of which is not lower than 1800° F., or 1500° F. for glass reinforced with wire mesh. The panels of glass should not exceed 2 ft. across and should be secured in frame of hardwood not less than 1¾ in. finished thickness or of iron. Broken panes should be replaced immediately.

(5) Floors should be of incombustible material. If wooden flooring is desired the wooden flooring should be laid solidly on the concrete without spaces between the wooden flooring and the concrete. The wooden flooring should not extend through any doorway openings forming connections with adjoining buildings.

(6) Any metal column or beam (except underside of the beams and edges of the flanges thereof) in an external wall or wholly or partly within a recess in a party wall should be protected with not less than 4 ins. of solid incombustible material executed with Portland cement and fixed close to the metalwork without cavities. All other constructional metalwork, including the underside and edges of flanges of beams in external and party walls should be protected with 2 ins. of solid incombustible material fixed close to the metalwork without cavities.

The internal protection to metalwork need not be provided in a one-storey building not exceeding 25 ft. in height.

(7) Staircases, lifts and any other floor perforations should be enclosed by brick walls not less than 8½ ins. in thickness or with reinforced concrete not less than 5 ins. in thickness and all openings in these walls should be fitted with fire-resisting doors arranged with automatic control.

(8) Windows should be glazed with glass conforming with that described above in respect of glazing in roofs and should be in panels not exceeding 2 ft. across either way.

(9) Doorways forming connections with adjoining buildings, where the buildings united by the openings will exceed a combined cubical extent of 250,000 cub. ft., should have the floor jambs and head formed of brick, stone, iron or other incombustible materials and be closed by two wrought iron or mild steel doors, sliding doors or shutters, each not less than ¼ in. thick in the panel at a distance from each other of the full thickness of the wall fitted to grooved or rebated iron frames without woodwork of any kind and all such doors, sliding doors and shutters should be fitted with sufficient and proper bolts or other fastenings and be capable of being opened from either side and shall have on each face thereof styles and rails at least 4 ins. wide and ½ in. thick and should be constructed, fitted and maintained in an efficient condition.

(10) The use of matchboarding for lining or similar purposes should be avoided.

(11) Apart from the above suggestions, building owners and/or their representatives should satisfy themselves that effective compliance with local Acts, Bylaws and/or Regulations is secured.

Fire-Resisting Doors.

The woods mentioned in the following schedule are suitable for use in the construction of fire-resisting doors. The frames of such doors should also be constructed in accordance with the schedule.

It should, however, be noted that wooden doors are effective against fire for a comparatively short period only.

SCHEDULE.

1. *Hard woods.* Oak, Teak, Jarrah, Karri, Indian Silver Grey Wood, Tasmanian Myrtle Wood, Andaman Paduak, Nigerian Iroko, Gold Coast Odum, African Walnut, Nora, Crabwood, Rhodesian Teak, Rhodesian Bean Mahogany, New Zealand Matai, Pyinkado, Andaman Pyinma, Queensland Maple, Secondee Mahogany, Red Moranti, English Ash, Douglas Fir, Keruing, Malayan Kapur, Borneo White Seraya, not less than 1¾ ins. finished thickness.

2. *Soft woods* which have been impregnated throughout with ammonium phosphate, subject to the following conditions:

(*a*) That the whole of the wood shall be thoroughly impregnated;

(*b*) That a door made of soft wood similarly impregnated and measuring 6 ft. by 3 ft. by 2 ins. thick shall resist the passage of smoke or flame when exposed to a temperature of 1,500° F., for a period of one hour, and that, when so exposed, the increase of temperature registered by an unshielded thermometer 12 ins. away from the outer surface of the door shall not exceed 10° F.

(*c*) That the thickness of the wood shall be at least 1¾ ins. and that, where this thickness is built up, the finished thickness shall be not less than 1¾ ins.;

(*d*) That all panels and boarding shall be properly tongued and grooved.

Fire-Resisting Substances.

Exhaustive tests seem to show that sulphate of aluminium is one of the best fire-resisting substances for wood, as it checks combustion by forming an infusible and non-conducting coating, while such substances as ammonium sulphate or ammonium phosphate when heated check combustion by emitting an incombustible gas.

The following is the formula for what is known as the United States 'Government whitewash mixture,' which also acts as a fire-retarding coating over interior wooden surfaces:—Slake a half bushel of quicklime with boiling water, keeping it covered during process; strain and add one peck of salt dissolved in warm water; put 3 lbs. ground rice in water and boil to a thin paste; ½ lb. of powdered Spanish whiting; 1 lb. of clean glue dissolved in hot water. Mix well and let it stand for several days. Keep the mixture in a kettle or receptacle, and apply as hot as possible with a whitewash or paint brush.

(See also p. 306, Vol. I.)

Fire Prevention at Sea.

The International Convention for safety of life at sea, 1929, drafted provisions for passenger-carrying ships which are now compulsory throughout the world. The regulations are obtainable from H.M. Stationery Office. Ship fires both afloat and in harbour have directed attention to the problem of ship protection and in consequence many vessels are now equipped with sprinkler systems, similar to those fixed in buildings or with an installation of CO_2 cylinders.

Air, when diluted with between 25/30 per cent. CO_2 at atmospheric pressure, will not support combustion and under the aforesaid regulations such concentration is required in connection with the fire protection of cargo and machinery spaces of passenger-carrying ships. For fire protection purposes it is stored in cylinders, from which it is released by the perforation or destruction of a metal disc closing the valve orifice, either by a hand or mechanically operated lever or by a supply of gas from a pilot cylinder, which is allowed to press on a piston in contact with the disc perforator.

Oil Fires.

The 'foam' principle is now generally adopted for the protection of storage tanks.

A suitable 'foam' may be made by mixing saturated solutions of bicarbonate of soda and aluminium sulphate with glue, liquorice powder, quassi bark, etc. The solutions when mixed produce foam in a bulk of approximately eight times their volume, which flow readily over the burning surface. Foam to an even depth of 6 ins. over the burning material will extinquish an outbreak in an oil tank.

The solutions can be stored in tanks, or they can be made as required in small tanks having a continuous and controlled water supply into which the dry ingredients are introduced by mechanical means at a desired rate. The two liquids, prepared separately, are pumped to the point where foam is required, or may be delivered by gravity or other means.

Another method for the continuous generation of foam, where a high-pressure water supply exists, is to insert the ingredients in the form of a single dry powder through an open-top hopper

into a chamber in which a partial vacuum is formed by the passage of water through a nozzle on the injector principle. The water supply enters at one end of the chamber and carries the powder from the opposite end into a pipe-line in which the foam is formed. Two machines of this character can be used to convey two separate powders to a distant meeting point where foam is formed.

The ideal to be aimed at is the formation of the foam as close as possible to its point of application to the burning liquid, and to deliver it with as little disturbance as possible of the burning surface.

Apparatus for the continuous generation of foam for City Fire Brigade use can be readily accommodated on an automobile vehicle, the water supply being obtained from street hydrants.

Another method for the production of foam consists in aerating water by mechanical means and introducing a small percentage of saponin, or like material, into the froth produced.

REFRIGERATION AND COLD STORAGE.

(pp. 719–749)

(Contributed by M E Anderson, A.M.IMech.E.)

SECTION XXXV

REFRIGERATION AND COLD STORAGE.

(Contributed by M. E. Anderson, A M.I.Mech.E.)

Principles.

Refrigeration is the removal of heat from air, water, brine or any other substance which it is desired to cool, and its transference to a suitable cooling medium—usually water, sometimes the atmosphere.

In the usual engineering sense of the term, refrigeration involves reducing the temperature of the air or whatever it may be below that of the cooling medium, and, as the Second Law of Thermodynamics states, this cannot be done without the expenditure of energy.

There are three principal systems by which this transfer of heat from a cold substance to a warmer one can be accomplished: the cold air machine, the absorption plant, and the vapour compression system. The first of these is now almost obsolete, though it has recently been revived for cooling aeroplane cabins, the second has a limited field of application, and the third is used in the great majority of cases.

The vapour compression cycle is a modification of the reversed Carnot cycle, which comprises the following four stages: adiabatic compression; isothermal compression with rejection of heat to the cooling medium; adiabatic expansion; isothermal expansion with absorption of heat from the substance to be cooled.

The coefficient of performance (ratio of heat removed to energy expended in heat units) of a plant working on the reversed Carnot cycle would be

$$\frac{T_1}{T_2 - T_1}$$

where T_1 is the temperature at which heat is removed from the substance to be cooled and T_2 the temperature at which heat is rejected to the cooling medium.

In the vapour compression system, the working substance is a fluid capable of being condensed at a temperature not much above that of the cooling medium and at a pressure not excessively high. The isothermal compression stage of the reversed Carnot cycle is replaced by a process of removal of heat at constant pressure, involving the condensation of the fluid; the adiabatic expansion is replaced by expansion through a regulating valve and the isothermal expansion by absorption of heat at constant pressure, involving evaporation of the fluid. As a result of these modifications, and particularly of the use of a regulating valve instead of an expansion cylinder, the coefficient of performance of the plant is always less than would be obtained on the Carnot cycle. The difference, however, is not very great in the case of all the generally used refrigerants except carbon dioxide, although it does become more marked the lower the evaporation temperature and the higher the condensation temperature.

A simple refrigerating apparatus would consist of a coil of piping immersed in brine, the piping containing a suitable liquid such as ammonia, and having the ends open to the atmosphere. The pressure in the coil being that of the atmosphere, the temperature of the ammonia would fall to the saturation temperature corresponding to 14·7 lb./sq. in. abs., *i.e.* -28° F., and at this temperature it would boil, absorbing heat from the brine. The limitations of such an apparatus would be (1) that a temperature lower than -28° F. could not be obtained; (2) that the refrigerant fluid would have to be constantly replenished in order to ensure a continuous supply of refrigeration.

The coil just described is a simple form of an apparatus which forms part of every refrigerating plant, the *evaporator*. The object of the other principal components is to overcome the limitations mentioned above. In order that the vapour leaving the evaporator may be recovered and used again, it must be liquefied. For this purpose its pressure must be raised to such a level that the corresponding saturation temperature is higher than the temperature of the cooling medium. This is the function of the *compressor* (fig. 1). From the compressor the hot vapour passes to the *condenser*, where it first loses its superheat and is then liquefied, giving up heat to the cooling medium—usually water, except in the case of small plants, which frequently have air-cooled condensers. The liquid leaving the condenser is now ready for re-use in the evaporator, to which it is admitted through the *regulator* or expansion valve, which reduces its pressure to that existing in the evaporator, and also controls its rate of flow in such a way that just so much is admitted as can be evaporated with the temperature difference prevailing at the time.

This regulation of the flow was effected by hand in older plants, but is now generally automatic, the regulator in such cases being usually one of three principal types: (1) low pressure float, maintaining a constant level of liquid in the evaporator or in a vessel which feeds it; (2) high pressure

float, keeping the condenser drained of liquid (this necessitates the charge of refrigerant in the plant being correct); (3) thermostatic (controlling the superheat of the vapour leaving the evaporator). Regulation should be such that no unevaporated liquid returns to the compressor; any such liquid causes a serious reduction in the pumping capacity of the compressor, because it is only partially vaporised on the delivery stroke of the piston, some liquid remaining in the clearance space at the end of this stroke and vaporising during the suction stroke. Ideally, the refrigerant leaving the evaporator would be in the dry saturated state; but in practice it is necessary that it

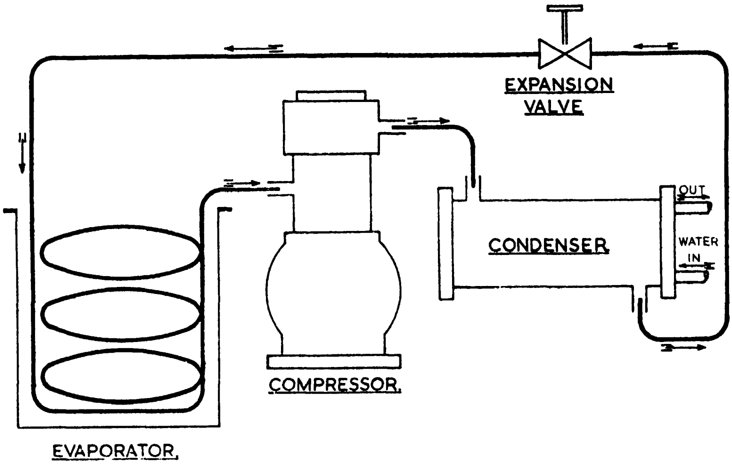

FIG. 1.—Vapour Compression System.

should be superheated to some extent, usually by at least 10° F., to ensure the complete absence of liquid.

In its passage through the regulator, the pressure of the refrigerant falls to that existing in the evaporator, and its temperature falls correspondingly; the heat thus removed from the liquid is used in evaporating a part of it, and the vapour so produced has to be pumped by the compressor, without providing any refrigerating effect, the coefficient of performance being thereby reduced. The proportion of refrigerant wasted in this way varies directly as the ratio of specific to latent heat, which should, therefore, be as low as possible. It does not in fact differ greatly for the various common refrigerants with the exception of carbon dioxide, for which it is exceptionally high.

Effect of Variation in Working Conditions.

The expression for the Coefficient of Performance on the reversed Carnot cycle shows that the ratio of refrigerating duty to power absorbed falls with decreasing evaporation temperature, and also with increasing condensation temperature. In the vapour compression cycle these effects are still more marked, because the loss through the expansion valve increases with increase in difference between the two temperatures.

Moreover, the refrigeration obtainable from a given compressor falls with decreasing evaporation temperature, and this would be so even with a perfect machine, because the refrigerating effect depends largely on the weight of vapour pumped in unit time, and this in turn depends on the density of the vapour, which decreases with the evaporation temperature and pressure. Again, the various losses which reduce the volumetric efficiency of the compressor (clearance effect, heating of gas during suction stroke, leakage past piston and throttling through valves), all increase with increasing difference between evaporation and condensation temperatures, so that the variations in performance with operating conditions to be expected from an ideal machine are still more marked in fact.

Tables I to IV, XIV and XIVA show the fundamental properties of various refrigerants, from which the evaporator duty obtainable from an ideal machine can be calculated as follows: Heat absorbed per pound = enthalpy of saturated vapour − enthalpy of liquid. Heat absorbed per cub. ft. pumped = heat absorbed per pound ÷ specific volume.

In order to determine the refrigeration obtainable from an actual machine, the ideal duty so calculated must be multiplied by the volumetric efficiency of the compressor. This is difficult to determine from first principles, and in the case of a new design experiment is the only safe guide.

Another use of the tables is, when the duty of a machine is known, to determine the volume and weight of refrigerant in circulation, for the purpose of fixing the pipe sizes.

It will be noted that in the case of carbon dioxide an additional table is included, showing the enthalpy of the liquid. This is necessary because the enthalpy of a liquid near its critical point (which for CO_2 is as low as 87·8° F.) depends not only on its temperature, but also to a large extent on its pressure.

Tables V to VII show the evaporator duty to be obtained from an actual machine, working with the principal refrigerants. The values shown are based on tests, but it will be understood that they must be regarded as a guide only, since variations in size, design and manufacture will considerably influence the volumetric efficiency. The machines on which the figures are based have a volumetric clearance of 3 to 4 per cent.

Horse-Power.

The indicated horse-power, *i.e.* the energy consumed in compressing and discharging the refrigerant, is given by the formula

$$\text{I.h.p. for 1,000 cu. in./min.} = 0 \cdot 00252 \frac{n}{n-1} P_1 \left\{ \left(\frac{P_2}{P_1}\right)^{\frac{n-1}{n}} - 1 \right\}$$

Tables X to XII have been calculated on this basis.

To find the i.h.p. absorbed by an actual compressor, the figures obtained from Tables X to XII must be multiplied by a factor corresponding to the work done by the re-expansion of the vapour left in the clearance space at the end of compression. This is always a matter of some doubt, since the precise extent to which the re-expansion departs from an adiabatic process cannot be known. Approximate values, however, are given in Table VIII.

When the i.h.p. has been obtained as described, the actual power required to drive the compressor (b.h.p.) is found by adding the friction h.p. The latter, naturally, depends to a considerable extent on design and manufacture; but approximate values for an average two-cylinder compressor are shown in Table IX.

Indicator Diagrams.

An indicator diagram, besides giving the only precise information as to the indicated horsepower absorbed by a compressor (area of diagram), also reveals any departure from good working conditions.

Fig. 2 shows a diagram from a good compressor.

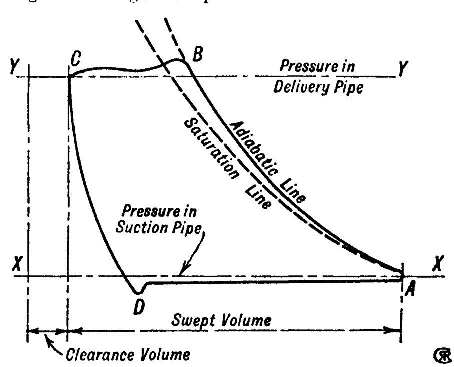

FIG. 2.

Defects are revealed as follows:

Liquid refrigerant drawn into cylinder:	Point D will lie further to the right.
Throttling through delivery valve:	Line BC lies too far (more than 1–2 lb./sq. in. above YY.
Throttling through suction valve:	Line AD lies too far below XX.
Delivery valve spring too heavy:	Peak at B is large.
Leakage past piston:	Line AB approaches saturation line.
Leaking suction valve:	” ” ” ” ”
Leaking delivery valve:	Point D will lie further to the right, and curve AB will be steeper than the adiabatic line.

Carbon Dioxide Refrigerating Machines.

CO_2 occupies a unique position in the group of fluids used for refrigeration in that its critica temperature, 87·8° F., often comes in the working range; also its specific heat is high, and its latent heat relatively low.

Its efficiency with condensing water at about 50° F. is less than that of the ammonia machine and falls away considerably with an increasing condenser temperature. There is, however, no break in the curves of capacity at the critical temperature.

CO_2 is odourless, and in mild concentrations can be inhaled without danger, but with concentrations of about 10 per cent. it may cause unconsciousness if inhaled continuously, and at higher percentages will produce suffocation.

The quantities used in machines are, however, such that even if the whole charge were to escape in any ordinary situation it is hardly likely to produce a dangerous concentration, and on this account the Board of Trade regulations permit CO_2 machinery to be installed in the engine room or similar space on board ship, whereas ammonia machines must be housed in a special deck-house.

CO_2 does not attack any metals, so that condensers can be constructed of copper piping, and these advantages have given it a predominant position for marine refrigeration.

Although the pressures are high, the diameters of all parts are small, so that there are no constructional difficulties.

The figures given in Tables XV and XVI are for ordinary CO_2 compressors of recent construction. They represent the average results that are obtained with compressors of moderate size, but performance and power naturally vary to some extent with the characteristics of different makes.

To obtain the best results in working, a CO_2 machine should run with the suction gas in a dry saturated state, or even slightly superheated. When leather pistons and gland packings were used, this was impracticable as the leathers were burnt by the temperature reached with dry compression. All modern CO_2 machines have piston rings and metallic gland packings, so that there is now no difficulty in running a CO_2 machine to give the best results that can be obtained.

With high condensing temperature the performance of a CO_2 machine can be appreciably improved by permitting the cooling of the liquid by its own partial evaporation to take place in two stages working as described below.

In this system the refrigerant splits up into two separate cycles. In the first or main cycle the liquid from the condenser passes through a regulating valve into a receiver where it is cooled by the evaporation of the liquid which is passing through the second cycle. The cooled liquid in the first cycle passes through a second regulating valve to the evaporator and thence to the compressor.

In the second cycle the liquid from the condenser passes simultaneously with the liquid in the first cycle into the receiver. It is then completely evaporated and in so doing cools the liquid in the first cycle. The vapour formed passes at a higher pressure than the vapour formed in the evaporator in the first cycle either to the main compressor or to an auxiliary compressor.

Characteristics of Refrigerants.

Ideally, a refrigerant should possess, among others, the following qualities :

High evaporator duty per cubic foot of vapour.
Moderate working pressures and pressure ratios.
Low delivery temperature.
Critical and triple points outside the working range.
Inert, non-toxic, non-corrosive, stable, non-inflammable.
Inexpensive and readily obtainable.

No refrigerant combines all these qualities.

Table XVII shows how the various refrigerants in common use comply with these requirements (except as regards toxicity and inflammability, which are dealt with separately).

TABLE XVII.

	Carbon Dioxide.	Ammonia.	Methyl Chloride.	Sulphur Dioxide.	Freon-12.	Freon-22.

Refrigerants classified in *descending order* of inflammability and explosivity :

(1) Hydrocarbons, Methyl formate } Lower limit of concentration 1 per cent. to 3 per cent. Upper limit 6 per cent. to 10 per cent. Violence of explosion similar to that of coal gas.
(2) Ethyl chloride $3\frac{1}{2}$ per cent. to 12 per cent.
(3) Methyl chloride 8 ,, ,, 17 ,,
(4) Ammonia 16 ,, ,, 24 ,,
(5) F-21, Methylene Chloride (Carrene No. 1) } Almost negligible risk.
(6) The other Freons, Carbon Dioxide, Sulphur Dioxide } Non-inflammable.

Refrigerants classified in *descending order* of toxicity :

(1) Sulphur dioxide	Highly toxic.
(2) Ammonia	,, ,,
(3) Methyl formate	
(4) Methyl chloride	Moderately toxic.
(5) Ethyl chloride, Methylene Chloride	
(6) F-21, F-113	Slightly toxic.
(7) F-11, Carbon dioxide	
(8) F-22	
(9) F-12, F-114	Non-toxic.

Other characteristics of commonly used refrigerants are as follows :

Ammonia.—This is still the most widely used refrigerant, especially for industrial and commercial applications. It does not mix with lubricating oils to any considerable extent, and as liquid ammonia is much lighter than oil, the latter can be readily drained off from an ammonia evaporator.

Ammonia shows slight traces of decomposition in both compression and absorption plants, but not to an extent sufficient to cause any serious trouble.

It does not attack metals, with the exception of copper and its alloys: phosphor bronze gudgeon pin bushes are, however, quite commonly used in ammonia compressors, and are not appreciably affected in the absence of moisture. Probably a film of oil acts as a protection in some measure.

Leakage of ammonia may be readily detected by Nessler's reagent. Ammonia is very soluble in water.

---

* Under U.S.A. Standard Ton Rating Conditions, 5° F. evaporation and 86° F. condensation. (C.o.P. on reversed Carnot cycle for these conditions : 5·74).

† Except for copper and its alloys.

‡ Especially in the presence of even small quantities of moisture.

Methyl Chloride.—This refrigerant is used to a considerable extent in small plants, its comparatively low working pressures simplifying construction. It is, however, tending gradually to be replaced by Freon-12.

Methyl chloride does not corrode the ordinary engineering metals in the absence of moisture, but when this is present corrosion is to be expected, particularly in the case of aluminium, zinc, and magnesium alloys. These materials should, therefore, never be used in methyl chloride plants, and every care should be taken to exclude moisture from the refrigerant circuit.

Liquid methyl chloride is miscible with oil and can only be separated from the latter by a distillation process.

Many organic materials are dissolved by liquid methyl chloride, and synthetic rubbers used for shaft seals must be carefully chosen.

Leaks of methyl chloride are best detected by the use of a soap and water solution applied to suspected points. The presence of traces of oil also often provides an indication of a leak.

Freon-12 (Dichlorodifluoromethane).—This modern refrigerant is being increasingly used, especially when safety is of paramount importance. As compared with methyl chloride, its disadvantages are a greater leakage tendency and the necessity for larger pipe sizes to avoid undue pressure drop (this arises because whereas the refrigerating duty obtainable from a given plant is practically the same with the two refrigerants, F-12 has about three times the density of methyl chloride, though only one-third of the latent heat). F-12 also requires considerably more condenser surface than methyl chloride, and, usually, slightly more power for a given compressor size. It is worth noting, therefore, that whereas a plant designed for Freon-12 can always be used for methyl chloride, conversion from methyl chloride to F-12 is not always possible without considerable modifications to the plant.

Freon-12 has no corrosive action on any of the usual metals, but is a solvent for some organic substances. Gaskets, shaft seals, etc., for F-12 may contain Neoprene or Chloroprene rubber, but not natural rubber.

It is quite stable under ordinary conditions, but will decompose, forming poisonous products, at high temperatures (above 1,000° F.).

F-12 is miscible with lubricating oil, being similar in this respect to methyl chloride.

It has only a slight odour, is non-inflammable and quite non-toxic, although, of course, if present in too large a quantity it will cause suffocation simply through exclusion of oxygen.

It has a higher leakage tendency than most refrigerants; leaks are detected by the change in the colour of the flame of a suitable ('Halide') torch. The same method is also sometimes used for methyl chloride, but not without risk, in consequence of the inflammable nature of the latter.

Calcium Chloride Brine.

TABLE XVIII.—SPECIFIC GRAVITY, CONCENTRATION, FREEZING POINT, AND HEAT CAPACITY.

Eutectic conditions :—Sp. gr. 1·303, concentration 31·4 per cent., temperature — 59·8° F.

NOTES :—

(1) Various authorities differ regarding the data for conditions near the eutectic point. The figures given here are due to R. S. Jessup.

(2) 'Specific Gravity' refers to the ratio of the density of the brine at 60° F. to that of water at the same temperature.

(3) The increase of density of calcium chloride brine at temperatures below 60° F. may be taken as very nearly 0·19 per cent. for each 10° F. reduction in temperature.

TABLE XIX.—WEIGHT OF COMMERCIAL CALCIUM CHLORIDE (70 PER CENT. $CaCl_2$) TO BE USED IN MAKING 1 GALLON OF BRINE OF VARIOUS DENSITIES.

Specific Gravity	1·20	1·22	1·24	1·26	1·28	1·30
Pounds per Gallon	3·74	4·13	4·53	4·95	5·38	5·80
Minimum working temperature recommended . .	5	0	−10	−20	−30	−40

The use of a secondary refrigerant or brine is often adopted when refrigeration is required for a number of cold rooms or other applications, as it permits these to be controlled individually without complication of the primary refrigerant circuit; and it is almost universally used for ice making, except in quite small units. It is also frequently employed as a form of 'refrigeration storage.' Calcium chloride is the salt used in the great majority of cases, and is suitable for temperatures down to − 40° F.

In deciding the density of the brine, account must be taken of the fact that fairly weak solutions are more corrosive than strong ones; for this reason, brine of a lower specific gravity than 1·20 should not be used.

Another important point in connection with the corrosive tendency of brine is the *p*H value. This should normally be kept between 8·5 and 10, by the addition of caustic soda when necessary; for this purpose a cresol red indicator paper, turning a violet colour at a *p*H value of 8·6, is useful.

Where zinc (or galvanised) parts are to be in contact with the brine, however, it is better to limit its *p*H value to 8·6, which can be done by adding the alkali cautiously until the test paper changes colour.

Cold Storage and Ice Making.

TABLE XX.—SHOWS THE TEMPERATURES MOST SUITABLE FOR THE STORAGE OF VARIOUS COMMODITIES.

STORAGE OF APPLES AND PEARS. REFRIGERATED GAS STORAGE.

Apples.

It has been found that many varieties of apples when stored at a temperature a little above freezing point (say 34° F.) develop an internal breakdown—if not in the store, then shortly after removal from it; while storage at higher temperatures is not capable of prolonging the life of the fruit sufficiently.

This difficulty has been overcome, as a result of the researches of Dr. Kidd and Dr. West, by using somewhat higher temperatures than 34° F., combined with storage in an atmosphere containing a considerable percentage of carbon dioxide with either a corresponding or a greater

reduction in the percentage of oxygen. The conversion of oxygen into carbon dioxide is effected by the apples themselves, and in cases where it is desired to reduce the oxygen content by more than the percentage of carbon dioxide required (*i.e.* when the combined percentages of carbon dioxide and oxygen are to total less than the percentage of oxygen in the atmosphere, 21 per cent.), the excess carbon dioxide is removed by circulating the air through a scrubber containing caustic soda or milk of lime.

Table XXI shows the temperature and the percentage of carbon dioxide and oxygen required for the principal varieties of apples. The first four varieties in the list must not be 'gas-stored.' It may also be noted that the variety Worcester Pearmain is usually kept in an ordinary cold store at 34° F.

TABLE XXI.—STORAGE CONDITIONS FOR APPLES.

Variety.	Carbon Dioxide. Per cent.	Oxygen. Per cent.	Temperature. ° F.	Remarks.
Annie Elizabeth	—	21	34	Must not be 'gas-stored.'
Blenheim Orange	—	21	34	
King Pippin	—	21	34

Laxton's Superb	10	2½	40	
Monarch	5	2½–5	39–40	
Worcester Pearmain	5	2½–5	34–35	

Pears.

The benefits of refrigerated gas storage as compared with ordinary cold storage are even more marked in the case of pears than in that of apples. Not only is the storage life greatly prolonged, especially if the percentage of oxygen is reduced, but the time for which the pears may be kept after removal from the store is approximately doubled.

Ice Making.

The method most usually employed for making ice is by immersing galvanised cans, holding up to 2 or 3 cwts. each, in a tank of brine. The cans are of various standard weights, and taper slightly to enable the ice to slide out freely. The greatest thickness commonly used is 11 ins.

The cans are arranged in rows placed on frames so that a row can be lifted at a time. The tank contains an evaporator coil compartment, and the brine is circulated through this and between the cans by means of a propeller.

The brine temperature required depends on the thickness of ice and the freezing time allowed and is given approximately by the equation $t = \frac{7d^2}{32 - \theta}$, where t is the time in hours, d the maximum thickness in inches, and θ the brine temperature in ° F. This applies where the brine is circulated at 30 ft. per minute between the cans. Brine temperatures usually held are from 10° to 15° F. Lower temperatures involve a risk of cracking the ice ; the temperature at which this happens depends to some extent on the analysis of the water.

Ordinary water frozen in a block without special precautions yields ice which is opaque owing to the minute bubbles of dissolved air entrapped in it ; the usual way of producing clear ice is to keep the water in motion while it freezes by the injection of a stream of air. This can be done at a pressure of 15 to 30 lbs. per sq. in. gauge through nozzles in the bottoms of the cans, the air delivery pipe running underneath a row of cans (high pressure air agitation system) or at about 2 lb. per sq. in. through drop tubes inserted from the top into the centre of the cans. In this case the drop tubes are removed shortly before the ice is frozen. Either system requires roughly ¼ c.f.m. of free air per cwt. of ice made.

As the ice formed spreads inwards from the side of the can, the salts dissolved in the water concentrate in the centre. The central core may be removed and filled with treated water to produce a perfectly clear block of ice.

When a row of cans has been frozen, it is immersed in a thawing tank containing warm water to release the blocks from the cans. These are then placed in a frame which tips them so that the blocks slide out ; the empty row of cans is filled in one operation from a filling tank.

The refrigeration required in this country for a fairly large tank, insulated with 6 ins. of slab cork, with brine at 15° F. and using water at 65° F., is about 215 B.Th.U.'s for each pound of ice.

Several special methods for making ice otherwise than in cans also exist.

In the ' Flakice ' system, ice is frozen in a thin layer on a revolving drum which dips into water and is refrigerated internally by brine. The ice is scraped off automatically.

Another American system, the ' Pakice ', uses a corrugated cylinder refrigerated externally, the ice being cut off continuously as it is formed. The crystals produced may be cemented into briquettes.

Fairly clear ice is produced in small quantities for use in drinks by freezing water in trays fitted with spacing grids so that the ice obtained is in cube form. The trays are placed in a unit comprising a series of shelves refrigerated by direct expansion. Ice 1¼ in. thick should be frozen in about 3 hours with evaporation at 5° to 10° F.

Insulation.

The thermal conductivities given in Table XXIII are laboratory values, and when calculating the heat leakage into a cold store, a liberal margin should be added to them to allow for imperfections in construction and the use of wood or other framework. With the usual insulating materials and methods of construction, the allowance required is usually from 30 to 50 per cent.

For insulation on board ship, a special allowance for the presence of steel frames, etc., must be made. Usually a value of about 0·07 B.Th.U.'s per hour per sq. ft. for a thickness of 10 ins. is in satisfactory agreement with results.

The calculation of heat flow through a compound wall is facilitated by the resistance concept —an analogy with Ohm's Law in electricity.

$$Q = \frac{\Delta t}{R_1 + R_2 + R_3 + \dots}$$

where Q = heat flowing in B.Th.U.'s per sq. ft. of insulation per hour, Δt = temperature difference between the two sides of the wall, R_1, R_2, etc., are the resistances of the several layers. The resistance is the reciprocal of the conductance, *i.e.* $R = \frac{d}{K}$, where d = thickness in inches and K = thermal conductivity in B.Th.U.'s per hour per sq. ft. per ° F. for 1 in. thickness (or d may be in feet and K expressed for 1 ft. thickness).

Example : Calculate the heat flowing through a 10-in. concrete wall insulated with 2-in. slab cork and lined with 1-in. deal. External temperature 70° F. ; internal temperature 50° F.

$$R_1 \text{ (concrete)} = \frac{10}{6\cdot7} = 1\cdot49$$

$$R_2 \text{ (cork slab)} = \frac{2}{0\cdot35} = 5\cdot72$$

$$R_3 \text{ (wood)} = \frac{1}{1\cdot1} = 0\cdot91$$

$$R_1 + R_2 + R_3 = 8\cdot12$$

$$Q = \frac{20}{8\cdot12} = 2\cdot46 \text{ B.Th.U.'s per hour per sq. ft.}$$

(Note that in this example the tabulated K of 0·27 for cork slab has been increased by 30 per cent. as explained above.)

For accuracy, surface resistances would have to be taken into account; but in most cases they are comparatively small, and it is usual to neglect them, the estimate of heat leakage being in consequence somewhat on the safe side. In the case of thin partitions, especially if made of materials of low insulating value, surface resistances should be included in the calculation.

It is good practice to base the calculation of heat load on the outside surface of a chamber; this again gives a small margin of safety.

The usual thickness of insulation used in this country—based on a calculation of the cost of the insulation and the refrigerating machine, and of the cost of running the latter—is about as follows:—

Temperature, ° F.	*Thickness, Ins.*
30 to 40	4
20 to 30	5
0 to 20	6
− 20 to 0	8

Cork slab is the most commonly used insulating material, combining the virtues of low thermal conductivity, ease of handling and permanence.

For special applications in which it is important to cool a chamber as quickly as possible, an insulating material of lower heat content is required, such as glass wool, Kapok, or one of the plastics.

TABLE XXIII.—THERMAL CONDUCTIVITY OF INSULATING MATERIALS AT 50 TO 60° F. (B.Th.U.'S PER HOUR PER SQ. FT. PER ° F. FOR 1 IN. THICKNESS.)

Material.	Density. Lb. per cu. ft.	K.
Aluminium foil (multiple layers, spaced)	3	0·25
Asbestos, tightly packed	44	1·6

INSULATION ON BOARD SHIP.

The insulation of cold chambers on board ship follows the same principles and method that apply to insulation work as carried out on land.

Owing to the way in which the ship's side and deck beams break up the surface, and to the absence of pure rectangular spaces, cork slabs are not so simple to use as loose filling materials. The use of cork slabs is extending.

Machinery.

COMPRESSORS.

Single stage compression is usual in this country for temperatures down to about $-15°$ or $-20°$ F., although Continental practice tends towards the use of compound compression for considerably higher temperatures than this.

The reciprocating type of compressor is used in the overwhelming majority of cases, the exceptions being the occasional employment of a multistage centrifugal compressor, usually for large duties and using a refrigerant of high specific volume, and the small rotary compressor sometimes used for domestic refrigerators.

Most compressors for ammonia, methyl chloride or freon are made single acting, and are of enclosed construction, with a crankcase at suction pressure and a gland of packed type or with smooth metallic rubbing faces (a carbon face is used in one pattern) fitted to the crankshaft. Cylinders and crankcase are generally made of cast iron.

Lubrication, except in quite small compressors of, say, 12 h.p. or less, is by a pump which circulates oil from the crankcase to the bearing surfaces including the gland. Preferably, though not usually, the oil supply to the cylinders should be independent.

Frequently, the compressors are of uniflow design, having trunk type pistons and, usually, automatically operating ring valves, the suction valves being fitted on the top of the piston. A safety head held down by a heavy spring is almost universally used; this carries the delivery valves and is capable of lifting and giving a greatly increased flow area, should it be subjected to an exceptionally high pressure. The risk of damage to the compressor in the event of a quantity of liquid refrigerant or oil entering the cylinder is thus greatly reduced. The provision of a safety head is particularly important in automatically operated compressors.

Vertical compressors usually have from 2 to 4 cylinders; a greater number, up to 16, may be arranged radially in some modern designs.

Cylinders of ammonia compressors are frequently water-jacketed, although the reduction in delivery temperatures thereby produced is not great. A water jacket is quite unnecessary in the case of compressors used for Freon-12.

The trunk pistons are usually made of cast iron, and except in small sizes (about 2 in. diameter downwards) are fitted with piston rings and, in the lower part, oil scraper rings.

Small compressors are frequently fitted with suction valves consisting of thin flexible strips of metal, with delivery valves either of similar design or of disc type.

Pistons in these small machines may be ringless, with benefit to the power absorbed, provided that the finish of pistons and cylinder walls is sufficiently fine, and that the clearance between piston and cylinder is not too great (it should not appreciably exceed 0·00025 in. per in. of diameter).

Carbon dioxide compressors are machined from high carbon steel forgings, owing to the high working pressures; stop-valves and other fittings are also machined from the solid. These compressors are often made double acting. The compressor rod gland is provided with a lantern supplied with oil at a pressure rather higher than the compressor delivery pressure. This is done by a special lubricator consisting of a cylinder with piston, oil being pumped by a hand pump (via a check valve) into the cylinder on the rod side of the piston and delivered to the lantern from this same side. The other side of the piston is subject to the CO_2 delivery pressure. Since the piston is balanced between the two forces, and the area on the rod side is the smaller, it follows that the pressure on this side is greater.

CONDENSERS.

The following types of condensers are used:

1. *Water-cooled.*

(*a*) *Submerged.*—This type, consisting of coils of piping contained in a tank through which water flows, is obsolescent, being replaced by:

(*b*) *Horizontal shell and tube.*—This widely used design consists of a cylindrical shell in which the refrigerant condenses on a number of tubes through which the water flows in one or more passes. The tubes are fixed to the end plates by expanding, welding, or brazing. Several such shells may be used if required. This type of condenser has taken the place of (*a*) owing to the much higher heat transfer coefficients obtainable and the consequent gain in compactness. Typical figures obtainable in practice for a water velocity of 4 ft. per second (which is normal) are:—

Ammonia =	215 B.Th.U.'s per	hour	per sq. ft.	per ° F.	
Methyl chloride =	160	,,	,,	,,	,,
Freon-12 =	135	,,	,,	,,	,,

(c) *Vertical shell and tube.*—In this case the water flows down the inner surface of the tubes in a single pass, without filling them. Its main advantage is probably economy of floor space.

With regard to the water quantity required for shell and tube condensers, this is usually calculated to give a rise of about 13° F. There is no doubt, however, that while this is good practice where water is re-circulated over a cooling tower, the use of considerably smaller quantities of water will result in economy of operation at normal costs of power and water where the latter is run to waste.

(d) *Double pipe condensers*, with water flowing through the inner pipe and refrigerant condensing in the annulus. These are now little used, being largely superseded by (b).

2. *Evaporative.*

(a) *Atmospheric.*—The type of condenser usually called by this name consists of piping arranged in vertical stacks, water being re-circulated over these from a tank beneath. They take up considerable space, and must be placed in a position exposed to the atmosphere but protected from the wind. The heat removed in a condenser of this type is used in evaporating the water, each pound of which is therefore capable of providing about 1,050 B.Th.U.'s cooling effect, so that the water consumption is only a few per cent. of that necessary for an ordinary water-cooled condenser. The condensation temperature obtained is, however, considerably higher and depends on the wet bulb temperature of the air.

(b) *Forced draught.*—This type of condenser is basically similar to (a), but provides more effective evaporative cooling by incorporating forced circulation of air over the pipes. Less surface is required, since the rate of diffusion of water vapour into the air is increased. The quantity of air to be circulated may be reckoned at about 1 cu. ft. per minute for every 50 B.Th.U.'s per hour of condenser duty to be removed.

Space may be further economised by the use of gilled instead of plain piping.

3. *Air-cooled.*

This type is made only in small sizes, as otherwise it becomes unduly large and also requires an unreasonably large volume of air. For small automatic machines up to 3 or 4 h.p., however, it is almost universal. It consists of one or more stacks of gilled tubing connected by headers at top and bottom; air is circulated over them by a propeller type fan. A liquid receiver is fitted.

EVAPORATORS.

These are of two main types : (a) air coolers, and (b) coolers of brine or water.

(a) When the evaporator cools air directly, the plant is said to operate on the direct expansion system.

In some cases, piping in the form of grids is arranged on the walls and/or ceiling of the room to be cooled. This arrangement is used mainly in cases where the heat load to be dealt with consists almost entirely of that passing through the insulation, and no appreciable cooling of the commodities stored is involved. It has the disadvantage of using a large quantity of piping, and defrosting is liable to be a rather messy operation.

A better method of cooling a store is in most cases to use a cooler consisting of a number of grids arranged in the form of a battery over which air is circulated by means of a fan. Air flow should be at right-angles to the pipes, in which case a heat transfer coefficient about three times that found with natural air circulation can be obtained. Except for quite small rooms, it is usual to arrange ducting to distribute the air fairly uniformly ; but it is also possible to dispense with the use of ducting in quite large rooms by installing one or more coolers each having above it a series of fan runners mounted on a horizontal shaft and projecting a stream of air across the ceiling, the air returning to the cooler near the floor.

In cases where the evaporation temperature is above 32° F., (as in air conditioning applications) the air cooler is frequently made of gilled tubing, resulting in a great saving in space occupied, and in refrigerant charge. This type of cooler is also sometimes used at lower temperatures where the stopping periods of the plant can be sufficiently numerous and extended to allow defrosting to take place.

A ' wet ' or brine spray cooler is suitable for use when the evaporation temperature is below 32° F. and considerable quantities of moisture have to be removed from the air. In this type of apparatus brine is recirculated through sprays and over the cooler, which not only prevents the formation of frost but also increases the effective cooling surface and so makes it possible to reduce the amount of piping by 50 per cent. or more.

The disadvantage is the necessity of continuously or periodically re-concentrating the brine in consequence of its dilution by moisture condensed from the air.

(b) The most usual type of evaporator for cooling brine or water to-day is the horizontal shell and tube pattern, very similar in design to the corresponding condenser, but usually fitted with a vertical branch of large diameter from which the vapour is drawn off, and which keeps the velocity of the vapour sufficiently low to avoid entrainment of liquid. Regulation of a plant fitted with such an evaporator may be effected by either a high pressure or a low pressure float regulator.

Submerged coil evaporators of simple design are also still used to some extent.

Another form of evaporator useful when considerable storage of water or brine is required consists of a rectangular tank containing rows of vertical tubes connected to headers at their upper and lower ends. The water or brine is circulated across the tubes at about 1 ft. per second.

When water has to be cooled to a temperature very near to its freezing point, a shell and tube cooler is not suitable, because of the risk of freezing the water in the tubes and bursting them. In such a case a cooler of the Baudelot type may be used; this is a surface cooler consisting of vertical coils over which the water is circulated at the rate of 1 to 2 galls. per minute per foot of pipe in the uppermost tier.

TEST PRESSURES.

Commonly used test pressures for the various parts of refrigerating plant are as follows:—

	Hydraulic. Lb. per sq. in.	Air Lb. per sq. in.
Carbon Dioxide (all parts)	3,000	1,500
Ammonia:		
Cylinders, and other parts subject to condenser pressure	600	350
Crankcases, etc.	300	175
Condenser and evaporator coils	1,500	500
Shell and tube condensers and evaporators	500	300
Methyl Chloride and *Freon*-12:		
Cylinders, and other parts subject to condenser pressure	350	200
Crankcases, etc.	200	150
Condensers and evaporators	350	200

Heat Transfer.

The importance of obtaining high coefficients of heat transfer lies in the fact that to obtain the best performance from the machine its evaporation and condensation temperatures must be kept as close as possible to those of the substance being cooled and the cooling medium respectively.

Most cases of heat transfer met with in refrigeration work are concerned with a pipe having air, water or brine on the outside and either (*a*) evaporating or condensing refrigerant, or (*b*) water or brine used as a cooling medium, on the inside. The total resistance to heat transfer is made up of fluid film resistances on the inner and outer surfaces, resistances of dirt and scale films, and resistance of metal, and the relative values of these resistances must be considered in assessing the effect of any change in conditions. In many cases the effect of the metal resistance is negligible, but this may not be so where the film coefficients of heat transfer are high, as in some condensers. Again, in air coolers or air-cooled condensers, the internal resistance, though not negligible, is usually so much less than that on the air side that the latter has by far the greater influence. Thus, although the film coefficient of condensing Freon-12 is much lower than that for methyl chloride, it is found that there is little difference in overall heat transfer in an *air-cooled* condenser for either of these two refrigerants. In a water-cooled condenser, on the other hand, the resistances of the water side and the refrigerant side are comparable, and the overall figure is therefore much lower in the case of Freon-12.

AIR COOLERS.

In cooling and dehumidifying air by means of a refrigerated surface, the sensible heat removed from the air has to be transferred through a film of non-turbulent air, the resistance of which governs the rate of heat transfer. The condensation of water vapour to liquid form, however, takes place only at the surface of the water film, not in the air itself, and therefore meets with no appreciable resistance. Hence it is correct to design the cooler surface on the basis of sensible heat transfer only. The proportion of the total duty that is sensible heat varies with the circumstances, but for normal cold store work probably averages about 80 per cent. In some air-conditioning applications it may be much less. The figures for air coolers given in Table XXIV apply to sensible heat transfer.

Once the sensible heat removed by a given cooler is known, the dehumidification effected can be calculated by the aid of two principles: (1) the ratio of moisture removal to temperature reduction remains constant as the air passes through the cooler, provided that the surface temperature is constant, which may be taken to be the case with a direct expansion cooler of plain pipe; (2) if the cooler surface were indefinitely prolonged, the air would eventually reach the surface temperature and would then be saturated.

In the case of extended surface (gilled) coolers, however, the problem is complicated by the fact that the surface temperature is considerably higher than that of the refrigerant, and varies in the direction of the air flow across the cooler.

TEMPERATURE DIFFERENCE.

When sensible heat is transferred, the temperature difference between the donor and the recipient of the heat is not in general the same in different parts of the apparatus. In this case it

is usual to use the logarithmic mean temperature difference for calculations; *i.e.* if D and d are the temperature differences at inlet and outlet (not necessarily respectively, but D representing whichever is the greater) -

$$\text{Logarithmic M.T.D.} = \frac{D - d}{2 \cdot 303 \log_{10} D/d}.$$

This is always less than the arithmetical T.D., which should not therefore be used if D is more than say $1 \cdot 3\, d$; for lower ratios of $\frac{D}{d}$ the difference between the two T.D.'s may be neglected for practical purposes. The use of the Log. M.T.D. is correct only if the specific heats are constant with the temperature variation involved, and if the coefficient of heat transfer is also constant. These assumptions are sufficiently close to the truth to be warrantable in most cases, but where they are not, the calculation must be broken down into suitable stages.

TABLE XXIV.—SOME TYPICAL HEAT TRANSFER COEFFICIENTS.

Air Coolers (Cross Flow).	Max. Air Velocity, ft. per sec.			Notes.

EFFECT OF VARIATION IN VELOCITY.

In the great majority of the cases of heat transfer dealt with by the refrigerating engineer, the flow of the fluids concerned is turbulent; in such cases the surface coefficient of heat transfer varies with a power of the velocity, *i.e.* (approximately) $h \propto v^{.6}$ for fluids flowing at right angles to pipes and $h \propto v^{.8}$ for fluids flowing along or through pipes. It must be borne in mind that such variations apply only to the particular film coefficient concerned, not to the overall coefficient.

EFFECT OF VARIATION IN PIPE DIAMETER.

For flow across pipes, $h \propto \frac{1}{d^{.4}}$ approximately; for flow through pipes, $h \propto \frac{1}{d^{.2}}$.

EFFECT OF VARIATIONS IN PROPERTIES OF FUIDS.

(*a*) *Viscosity.*—For flow across pipes, $h \propto \frac{1}{\mu^{.3}}$ approximately; for flow through pipes, $h \propto \frac{1}{\mu^{.45}}$ approximately.

(*b*) *Density.*—Flow across pipes, $h \propto \rho^{.6}$. Flow through pipes, $h \propto \rho^{8}$.

When considering the effect of changes in density, as in the case of air at various pressures, it is helpful to remember that the heat transfer coefficient actually depends on mass velocity, *i.e.* on the product ($v\rho$).

Automatic Refrigerating Machines.

Domestic refrigerators working on the vapour compression system are now always automatically controlled, as are the great majority of small machines (up to 4 or 5 h.p.) used for commercial and industrial applications.

Ammonia has been almost entirely replaced for these small plants by methyl chloride or Freon-12. Sulphur dioxide was used to a considerable extent not long ago but is now seldom met with.

The compressor has most usually 2 or 3 cylinders, and presents no special features of design as compared with larger ammonia machines, other than simplicity of construction (an oil circulating pump is not used, lubrication being mainly by splash, but in some models helical grooves cut in the crankshaft convey the oil to the bearing surfaces) and the universal use of a packless crankshaft gland. The latter varies in design, but its essentials comprise a rubber, composition, or white metal sleeve fitting tightly to the crankshaft to prevent leakage along the latter, and two rubbing faces, one fixed to the gland cover and the other rotating with the shaft. The rubbing faces may be of bronze and steel, or one may be of carbon. A spring is used to press them together, and some measure of flexibility is essential to ensure perfect contact. This may be obtained by a metal bellows fixed to the cover at one end and to one rubbing member at the other, the spring being between the two end pieces, or the rubber sleeve may be prolonged in the form of a bellows ending in the rotating member, one end of the spring being in contact with this assembly and the other with a collar on the shaft.

Usually no oil separator is fitted, the oil circulating through the system and returning again to the crankcase; the velocity of the vapour in the evaporator and suction line must be sufficient to carry the oil through. In most cases the direct expansion system is used, but it is not advisable to try to obtain accurate temperature control of more than two or three chambers on this system using only one compressor.

REGULATION AND CONTROLS.

A thermostatic regulator is generally used, its function being to ensure that the vapour leaving the evaporator is slightly superheated. This results from the fact that the needle valve is balanced between a force exerted by the pressure at the evaporator outlet and one corresponding to the temperature there, the latter being produced by a suitable fluid—usually that with which the system is charged—contained in a phial attached to the suction line. Should several evaporators be connected to the same machine, each will have its own thermostatic regulator.

A single cold chamber or other unit is controlled by a thermostat, stopping and starting the machine according to the temperature; the usual difference between starting and stopping temperatures in a commercial instrument is about 4° F. Another method often used in the U.S.A. is to control by a pressure switch ('pressostat'); variations in evaporation temperature (and thus pressure) following those of chamber temperature, it is possible to set the pressure switch so that the chamber temperature is maintained between required limits, at least until some considerable change in external conditions occurs. This method is not much favoured in Britain, where the 'pressostat' is used mainly as a safety device to stop the compressor should unduly low evaporation temperatures be reached.

Where two or three units have to be automatically controlled from one machine, this control can be effected by fitting a solenoid-operated stop-valve in the liquid line leading to each regulator. The controls are wired so that each thermostat is capable of starting the machine and opening the liquid stop-valve corresponding to it own chamber; when all thermostats are 'cut out,' the machine stops.

Should two units of widely different temperatures have to be dealt with by one machine, it is necessary, in addition to the two regulators, solenoid valves, and thermostats, to provide a constant back pressure valve in the suction line from the higher temperature unit and a check valve in that from the lower temperature unit. The back pressure valve prevents the temperature of the evaporator to which it is connected from being undesirably low, while the check valve prevents the charge of refrigerant in the higher temperature evaporator from passing into the lower temperature evaporator and thereby warming it during the stopping periods of the machine; in the absence of the check-valve this would happen as a result of the difference in pressure existing.

Most small automatic plants (other than those installed on board ship) have air-cooled condensers; but when a water-cooled condenser is fitted, a pressure switch arranged to cut out on rise of pressure and connected to the delivery side of the compressor should be fitted, so as to stop the machine should the failure of the water supply give rise to an unduly high pressure. Such a safety device is often omitted in the case of an air-cooled condenser with a fan driven by the compressor motor; but should the condenser be remote from the compressor and have its own fan and motor, stoppage of the latter would lead to excessive pressure, which should be guarded against by the provision of a pressure cut-out switch.

When a water-cooled condenser is used with an automatic plant, an automatic water valve to control the water supply is also fitted. This may be simply a solenoid-operated valve, opening when the machine starts and closing when it stops; or it may be a modulating valve operated by the condenser pressure, opening when the latter reaches a given value.

Automatic control is now often used in conjunction with quite large compressors. In such cases it is important that the plant shall be so arranged that there is no chance of liquid being drawn into the compressor, as it is dangerous for this to be allowed to happen frequently, even though safety heads are fitted. This is ensured by what is known as the flooded or dry compression system, which also provides an excellent heat transfer coefficient between refrigerant and pipe wall. The essential feature of this system is that the refrigerant circulates through the coils at a rate several times as fast as that at which it is evaporated. The coils are fed with liquid refrigerant from a reservoir vessel, a mixture of liquid and vapour returning to the latter from the coils. The circulation may be by gravity only, being ensured by the buoyancy of the vapour formed; or in the case of long leads from the vessel to the coils being involved, a pump may be used. In either case, the vessel, besides feeding the coils, acts in its upper part as a liquid separator, the velocity of the vapour here being low enough to ensure that drops of liquid will not be entrained.

The flooded system is widely used on large plants, whether automatic or not.

Electrolux System.

This, used for domestic refrigerators, is a special application of the absorption cycle. In the basic form of the latter, the liquid refrigerant, usually ammonia, absorbs heat in an evaporator and is converted into vapour just as in a compression system. After leaving the evaporator, however, it enters an absorber, where it is dissolved in water. The strong solution is pumped to a generator at high pressure, in which by the application of heat the ammonia vapour is expelled, leaving a weak solution which returns via a pressure reducing valve to the absorber. The expelled vapour is liquefied in a condenser and returns through a regulating valve to the evaporator.

The Electrolux system is fitted with several auxiliary devices to improve efficiency, but its most important special feature is that it has no expansion valve and no circulating pump, and the pressure in all parts of the system is approximately the same. This is achieved by taking advantage of the fact that the pressure of the vapour of a liquid is independent of the presence or absence of a gas, non-condensible at the pressure and temperature prevailing, mixed with it. The evaporator of the Electrolux system contains hydrogen (prevented from entering the condenser by a liquid seal) and since the total pressure in evaporator and condenser is the same, the pressure of the ammonia in the evaporator is much lower, and the required evaporation temperature is thus obtained. The circulation of ammonia vapour and hydrogen to the absorber, and the return of hydrogen to the evaporator, are produced automatically by virtue of the difference in densities.

The weak solution of ammonia is transferred from the generator to the absorber as follows: the bubbles of vapour liberated by the action of heat (which may be by means of gas or electricity) carry the solution up to a separating vessel, from which the vapour passes to the condenser while the solution flows by gravity to the absorber.

Rating, Testing and Operation of Refrigeration Plant.

Rating.

The refrigeration produced by a plant is often stated in Tons Refrigeration. The Ton Refrigeration is the number of B.Th.U.'s which must be removed from 1 ton of water at 32° F. in order to convert it into ice at that temperature. In nearly all cases the U.S.A. ton of 2,000 lb. is referred to, and the latent heat of freezing of water being 144 B.Th.U.'s per lb., 1 ton of refrigeration is equivalent to $\frac{2,000 \times 144}{24}$ or 12,000 B.Th.U.'s per hour.

The refrigerating duty of a given machine may be quoted in tons under any conditions of evaporation and condensation, provided that these are clearly specified. There is, however, a

standard set of conditions, *i.e.* evaporation 5° F. (− 15° C.) and condensation 86° F. (30° C.); these are known as Standard Ton Rating conditions, and it is usually at these conditions that different refrigerants, for example, are compared. For completeness, the temperatures of the liquid leaving the condenser should also be stated, and it is important that this should be done in the case of carbon dioxide.

Lloyd's definition of the Ton Refrigeration is similar to that given above, except that the English ton of 2,240 lb. is used, so that the ton refrigeration is equivalent to $\frac{2,240 \times 144}{24}$ or 13,440 B.Th.U.'s per hour.

It should be borne in mind that the duty specified as obtainable at stated evaporation and condensation temperatures defines the output of the compressor only. The evaporation and condensation temperatures actually obtaining in practice, and hence the refrigerating duty produced, will depend not only on the temperature of the air or other substance being cooled and on that of the cooling water, but also on the evaporator and condenser surfaces provided and the coefficients of heat transfer obtainable from them.

Testing.

There are several ways of ascertaining the refrigerating duty obtainable from a given compressor, of which these may be mentioned :

(1) A brine cooling evaporator may be used and the rate of flow of the brine and the drop in temperature measured (see Table XVIII for heat capacity of brine). For equilibrium conditions, heat must be put into the brine in another part of the circuit, *e.g.* by an electrical heater or by steam-heated coils, at the same rate as that at which it is removed, and by measuring the heat input here, a check on the refrigerating duty may be obtained.

(2) The brine may be kept stationary instead of being circulated, and the rate of heat input adjusted until the brine temperature remains constant. The heat input being then measured by electrical instruments in the case of electric heaters, or by measuring the rate of condensation in the case of steam heaters, gives the refrigerating duty. The disadvantage of this method is that there is no independent check on the result.

(3) The rate of flow of liquid refrigerant arriving at the regulator may be measured by one of several methods, and the refrigerating duty then calculated by the aid of the enthalpy tables.

Brake horse-power may be ascertained by measuring the electrical input to the motor, provided that the efficiency of the latter is precisely known. It is better, however, especially in the case of small compressors, to use a dynamometer.

Operation.

Before a plant is put into operation, it should be tested for leaks under air pressure, and then evacuated of air, using the compressor as a pump for this purpose. The refrigerant is then charged into the inlet side of the evaporator, the charge being completed while the plant is actually running.

Before starting a non-automatic plant, care should be taken to make sure that the delivery stop-valve is open, that the oil level in the compressor is correct, and that the gauge valves are open ; also that the water is running through the condenser, and the cylinder jackets if any, and that the air, water or brine to be cooled is in circulation. In some cases a by-pass between the suction and delivery sides of the compressor is provided so that the motor does not have to start under load.

In judging the running of the machine, the most important indications are those given by the gauges. These are marked, in addition to the pressure scales, with scales showing the corresponding saturation temperatures for the refrigerant in use ; these scales show the actual temperatures of evaporation and condensation respectively (except in so far as the pressures at the gauge may differ from those existing in the evaporator and condenser as a result of pressure drop in the pipe lines).

The object of the operator of the plant is at all times to have the evaporator gauge reading as high as it can be consistent with the avoidance of liquid being drawn into the compressor, for on this depends the production of the greatest possible refrigerating effect ; and the condenser gauge as low as possible consistent with the presence of a sufficient charge of refrigerant and with the avoidance of an unduly high consumption of water, for in this way the power absorbed will be kept to a minuimm.

Regulation and refrigerant charge are to a considerable extent interdependent, and both must be correct.

For a plant working at an evaporation temperature below 32° F., the rule of thumb method of regulating, so that the frost line on the suction pipe extends up to but not on to the compressor, is excellent. A more scientific method of regulation is in accordance with the temperature of the refrigerant in the suction line. If this is equal to the evaporator gauge reading, it is a virtual certainty that unevaporated liquid is returning to the compressor, and the regulator should therefore be closed in until several degrees of superheat—usually at least 10° F.—are indicated by the thermometer. If there are several evaporator circuits to be regulated, the suction temperature method is the only one which will ensure maximum efficiency. These remarks apply where hand regulators are fitted ; float regulators are automatic in operation. Thermostatic regulators are

also automatic, but may require careful initial setting to provide a superheat suitable to the particular conditions.

Refrigerant charge must be sufficient to ensure that the refrigerant arriving at the regulator is entirely in liquid form. An excellent way to ascertain whether this is so is by the use of a sight glass in the liquid line: it should be completely full of liquid. Otherwise, it is often difficult to be sure that a plant is fully charged; rule of thumb methods, such as that the condenser gauge should be a given number of degrees higher than the water inlet or outlet temperature, are of limited application.

Where a condenser capable of providing some sub-cooling of the liquid—*e.g.* a horizontal shell and tube condenser with some tubes near the bottom of the shell—is fitted, a thermometer indicating the temperature of the liquid leaving the condenser will give a good indication; if its reading is slightly below the condenser gauge, the plant is sufficiently charged.

Of course, if the duty of the plant can be measured and proves to be equal to the known capacity at the working conditions, that in itself is sufficient proof that the charge is adequate.

In general, excess of charge will do no harm until the point is reached at which an appreciable proportion of the condenser surface is submerged by liquid and therefore unable to fulfil its function, in which case the condenser gauge will be higher than it should be. If a liquid receiver is fitted to the condenser, it is possible to run with a charge considerably greater than the minimum without ill effect. It is always better to work with slightly too much than with too little refrigerant.

If the regulator is of the high pressure float type, however, almost the whole charge must be in the evaporator, and the amount is, therefore, rather critical; if it is insufficient the evaporator gauge will be abnormally low and the suction superheat high, while if it is too great the machine will run ' wet,' *i.e.* unevaporated liquid will reach the compressor.

If a plant works under fairly constant temperature conditions, and the condenser gauge reading for correct working has been ascertained, the indication of this gauge will in future be a useful guide. If it is abnormally low, and the plant is not ' running wet,' there is insufficient charge. An abnormally high condenser gauge may be due to excess of charge, or on the other hand it may be caused by the presence of ' non-condensible ' gas, usually air, in the system. This may occur through leakage in at the gland if the evaporation pressure is below that of the atmosphere. It is remedied by purging, *i.e.* allowing gas to escape through a connection at the top of the condenser. It must be borne in mind that air cannot be expelled without loss of refrigerant vapour also. This loss can be minimised by first allowing the mixture of vapour and air from the condenser to pass into a purging vessel, where by the use of a coil at the evaporation temperature some of the vapour is condensed, leaving a mixture with a higher proportion of air.

Apart from maintaining the correct charge of refrigerant and correct regulation, and keeping the system free from air, operation will include attention to the oil level in the crankcase (oil separators may be provided with automatic means of returning oil to the crankcase, or this may have to be done by hand) and to the compressor gland. A suitable oil for use in the crankcase will be specified by the makers of the compressor, and it is essential to adhere to their recommendations—the oil must have sufficient ' oiliness,' yet not freeze in the evaporator.

Refrigeration on Board Ship.

The use of refrigerating machinery on board ship may be roughly subdivided into four main groups:—

(1) Small plants to cool provision rooms and to make small quantities of ice.

(2) Large passenger vessels with large provision rooms and numbers of cold cupboards throughout the ship and perhaps some refrigerated cargo.

(3) Large vessels used primarily for refrigerated cargo.

(4) Air conditioning.

CO_2 refrigerating machines are largely used for all classes and sizes of machines and evaporative liquid cooling of the CO_2 is sometimes employed as it results in economy in working particularly when the condenser water temperature is high.

In Classes (1) and (3), the machines are usually driven by an electric motor.

In Classes (2) and (4), most of the older steam-driven ships have the main refrigerating machinery driven by a compound tandem steam engine which incorporates its own steam condenser in the machine base. In motor-driven ships the drive is either by an electric motor or occasionally by a diesel engine direct coupled to the crankshaft of the refrigerating machine or through speed-reducing gears. The almost complete electrification of modern ships, whether driven by steam turbines or oil engines calls for a more compact design of refrigerating machinery which is electrically driven. Some of the larger ships have an insulated capacity of upwards of 600,000 cu. ft. and a typical arrangement of the refrigerating machinery is shown in fig. 8 (p. 747).

Cooling of Chambers.

It is usual to cool the chambers by means of cold brine circulated through 1¼-in. brine pipes. These pipes can be arranged on the roof and sides of the cold chambers, and this is the system used on most of the old vessels.

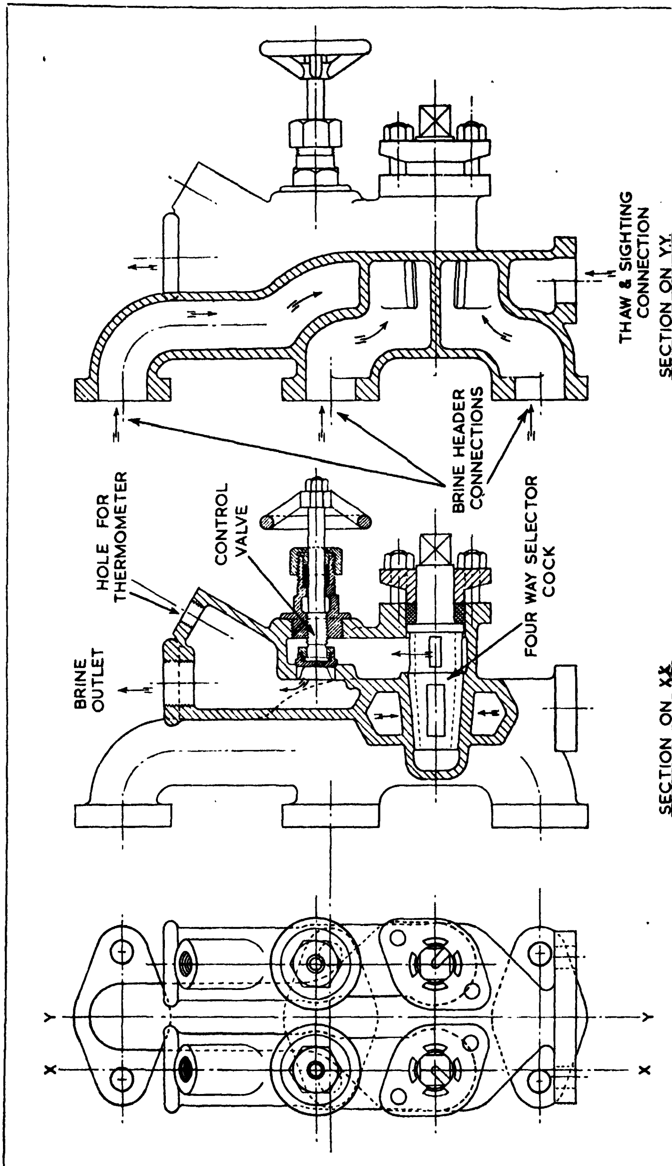

FIG. 5.—Duplex Four-way Selector Cock.

The present practice, however, is to arrange the pipes in the form of an air cooler, or battery, at one end of the cold chamber. Air is cooled by passing it over the cold pipes in the air cooler by means of a fan and then distributing the cold air throughout the space as desired.

It is sometimes found desirable to use both methods.

It is now usual to use a closed brine system where the brine is drawn from the evaporator by a pump, circulated through one or more circuits in the chamber to be cooled, returned to a closed header, and from this to the evaporator. The whole system is under a head of brine for which purpose a balance tank is fitted just above the highest level of the brine in the system. Thus there is no point where air can leak into the brine system which can therefore be kept free of air.

The multi-temperature brine system: When fruit, chilled and frozen meat are all carried in the same vessel, it is necessary to provide brine at a temperature best suited to each produce carried. Thus a modern ship may require brine at zero F. for freezing, brine at 20° F. for chilling and brine at any desired higher temperature for fruit. For thawing coolers and grids still higher temperatures are required. In large installations different evaporators are used for each temperature. The arrangement is shown diagrammatically in fig. 7, p. 746.

In both cases the brine pipes are arranged in a number of circuits of limited length, so that the return temperatures shall only show a small rise, and each of these circuits is separately controlled.

In some installations, the brine returning from the piping in the chill and fruit spaces is pumped directly back to the chilling delivery header and the heat absorbed by the brine in its passage through the chilling circuits is eliminated by means of an injection of freezing brine into the chilling system, the excess of brine thus carried in the chilling system being automatically returned into the freezing system.

Fig. 5, p. 744, shows the sectional arrangement of a duplex four-way selector cock and fig. 6, below, shows a section through the brine feed and return headers with the selector cocks mounted

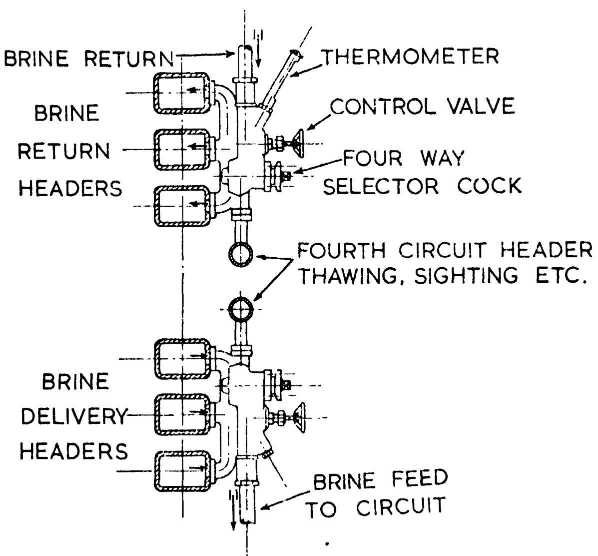

FIG. 6.—Arrangement of Brine Headers.

thereon. The two halves are quite separate as far as flow of brine is concerned, each double cock serving two circuits, and they are made in one casting for convenience. The two halves have individual control or shut-off valves and selector cocks, the headers being common to both.

Thermometers are fitted on the brine return fittings, but in order to keep the delivery and return cocks interchangeable, the bosses for the thermometers are plugged on the delivery cocks.

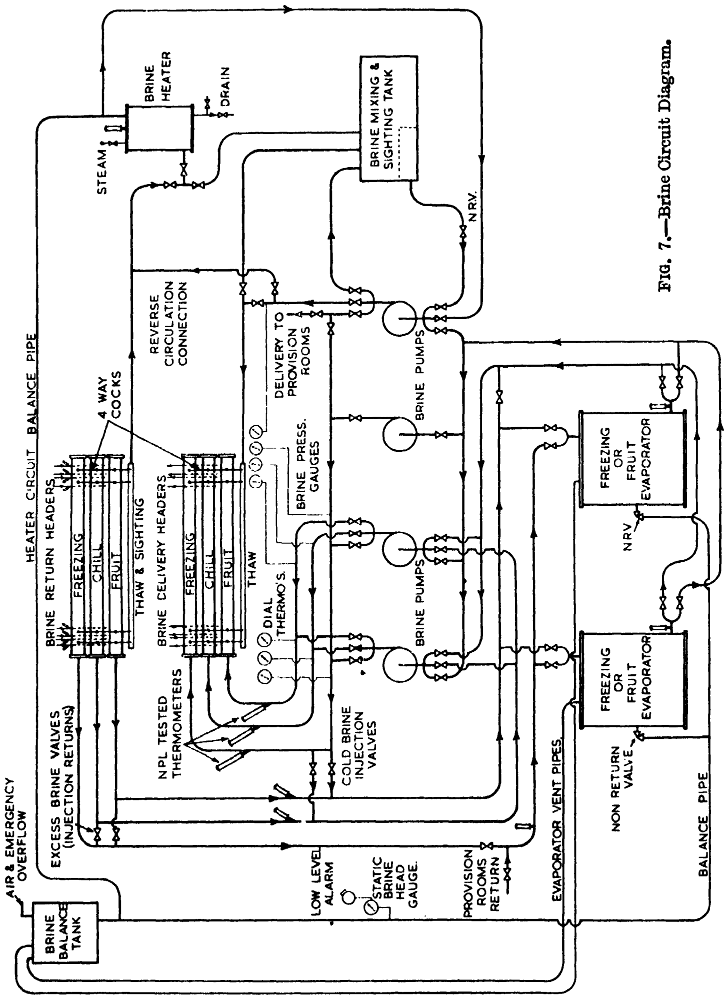

FIG. 7.—Brine Circuit Diagram.

One of the four circuits, usually the thawing circuit, is arranged for auxiliary duties, sighting, brine making, etc.

A connection is taken from the thawing return to the brine-making tank.

If there is a doubt as to whether any circuit is flowing freely or is being choked by foreign matter, the return cock of that section can be set to discharge into a tank where the flow can be observed.

It will be noticed on reference to fig. 7 that a tank is fitted to contain the surplus brine due to increase in volume caused by higher temperatures when thawing down the refrigerated chambers after unloading cargo.

A large modern installation may involve up to about 200 separate brine circuits, and the control room for a closed brine system is shown in fig. 9.

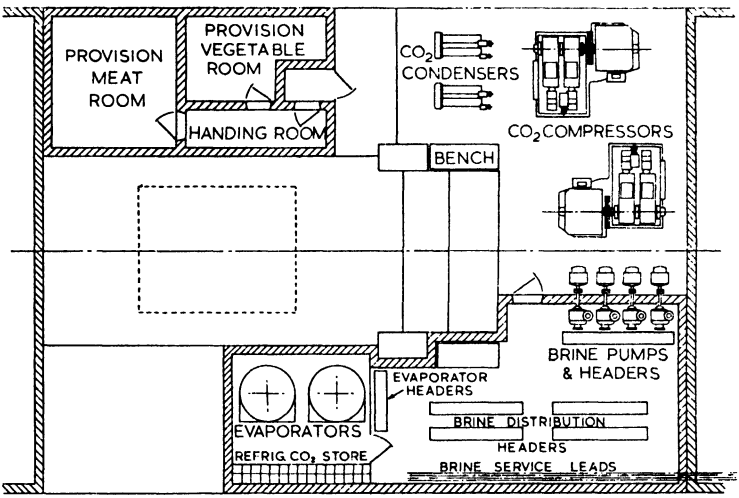

FIG. 8.—Refrigerating Plant on Board Ship.

The refrigerating machinery for these installations always consists of at least two units, each complete with its condenser and evaporator, and capable of independent working, each being of sufficient capacity to maintain the required temperatures in the cargo spaces at sea if the other is out of action. In most large plants there are three machines, two of which have ample power to maintain the cargo, with one independent unit in reserve.

The carriage of fruit, which is a living organism, demands air circulation to remove the heat given off by it due to respiration and to cool down the fruit, as, in many cases, it is delivered warm to the ship. A supply of fresh air must be introduced in order to control the CO_2 content of the air in the space. The air is cooled in a battery or cooler, and is distributed through the holds by ducts on the walls and buried in the insulation between the beams of the deck. A typical arrangement of an air-cooled hold is shown in fig. 10 which is taken, by permission, from the article by Messrs. Ormiston & Farmer on 'The Running and Maintenance of Marine Machinery,' published by the Institute of Marine Engineers. With these vertical air systems no dunnage is required except on the floor, where it serves to take the air away to the suction openings at the sides. The air ducts on the sides of the space are divided horizontally, the upper half being the delivery and the lower the suction. When the system is at work the air is drawn into the suction duct through openings near the deck, passes over the coolers, and is discharged into the delivery duct, from which it passes into the ducts already referred to in the deck insulation. These overhead ducts are perforated with 2-in. holes, and the air is discharged downwards through them, through the cargo, and finds its way into the suction duct to repeat the process. The square of the hatch is refrigerated by air blown through pipes as shown.

The system of air distribution shown in fig. 10 was introduced by J. & E. Hall, Ltd., and is now fitted to most modern ships. In this the sides of the hold are completely screened. This screening is divided vertically at frequent intervals so that the air passes from the bottom of the hold to the main suction duct and so to the coolers. The cooled air is distributed from main delivery ducts on the underside of the deck above, and particular care is taken to distribute cold air in front of the bulkhead. This system is used for the carriage of all types of refrigerated produce such as meat in frozen and chilled condition, fruit and cheese, and no dunnage is required except on the floor.

FIG. 9.

Another system of cooling with which many of the older ships for mixed cargo are fitted, is called the screened grid system. The grids on the side of the hold are shielded by timber screens which form a duct, with openings for air at intervals. The air is circulated by a fan which draws it from the duct at the end and delivers it to the ducts at the side of the hold. It is now out of date except for the smallest cargo spaces.

Heat Pumps

The use of a vapour compression refrigerating plant as a means of heating is a fairly obvious application, since its function is to remove heat from one substance and transfer it to another, and in fact the heating of houses by this means was suggested by Lord Kelvin as early as 1852.

There is no essential difference either in the principal components or in the method of operation between a refrigerating plant and a heat pump; the term '*reversed* refrigeration cycle,' often applied to the latter, is quite misleading. The only difference is that in the refrigerating plant the user's interest is in the evaporator or heat absorption side of the installation, whereas in the heat pump it is the condenser or heat rejection side that is important, and the pressure here must be adapted to the temperature at which the heating medium is required. It is, however, quite possible for the same installation to be in use simultaneously as a refrigerating plant and as a heat pump. Indeed, the most economical application of the heat pump occurs where the refrigeration

can be utilised, either simultaneously, or at a different time, as when a building is heated in winter and air-conditioned in summer.

It is natural that the idea of the heat pump should be attractive, particularly when fuel is as scarce as it is at the present time, because by its aid several units of energy in the form of heat can be obtained for the expenditure of one unit of electrical energy to drive the compressor.

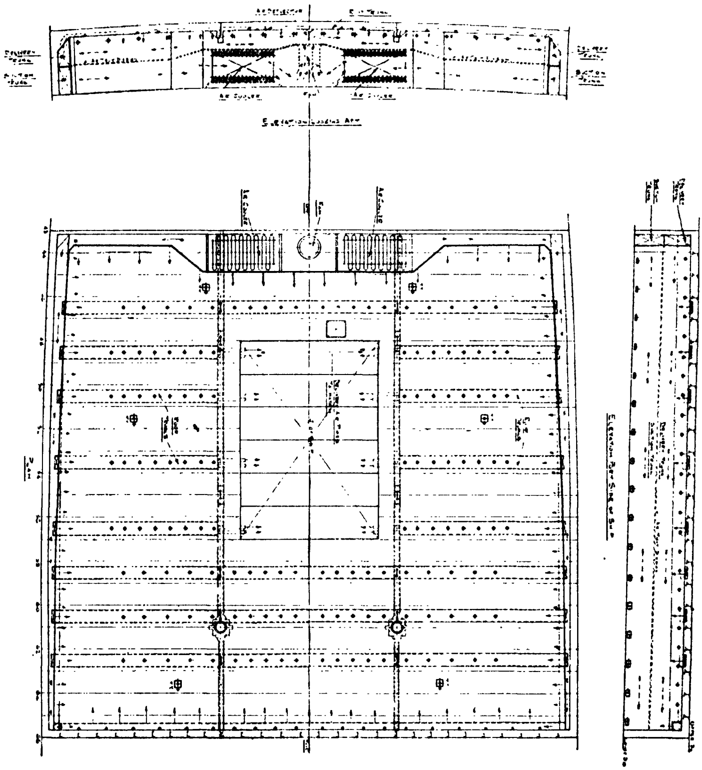

FIG. 10.—Arrangement of Tween Deck with Twin Battery and Vertical Air Circulation.

There are, however, a number of facts which tend to discourage the adoption of the heat pump, *i.e.* (1) The high first cost of the plant ; (2) the efficiency of production of electrical energy is low, so that one unit of energy in the form of electricity requires very much more coal than the same amount of energy as heat produced by the direct combustion of coal.

(3) The advantage ratio (heat produced ÷ energy consumed) of a heat pump depends on operating conditions : in order that it should be high, the condensation temperature must be low, which involves the use of large heating surfaces, and the evaporation temperature must be high, whereas in fact (4) the source of heat is usually coldest just when most heat is required. The two most readily available sources are rivers or lakes, and the atmosphere.

Heat pumps have been used mostly in the U.S.A., and also in Switzerland, where coal is very scarce, water power for the production of electricity is abundant, and lakes form a readily available source of heat. Even in such cases, however, it has usually been found necessary to supplement the heat pump by a conventional heating system during the coldest weather.

Table XXV gives an approximate idea of the advantage ratio obtainable with either ammonia or Freon-12 under various working conditions. The figures are based on actual results, and give the ratio of heat produced to actual energy input to the electric motor.

TABLE XXV.—ADVANTAGE RATIO OF HEAT PUMP.

AIR COMPRESSION

P = absolute pressure.
p = gauge ,,
v = volume of gas at pressure P.
B = barometric pressure, in the same unit as P and p.
T = absolute temperature.

Let suffix 1 be initial condition.
,, ,, 2 be final condition.

$P = p + B = p + 14 \cdot 7$ lbs./sq. in. for normal atmospheric air.

Isothermal compression and expansion.—In an isothermal change of conditions the temperature remains constant, *i.e.* T = constant.

hence PV = constant = RT (Gas Law)
or $P_1 v_1 = P_2 v_2$.

$$\text{and } \frac{P_1}{P_2} = \frac{v_2}{V_1}.$$

The horsepower required to compress and deliver gas isothermally (or the horsepower obtained by expansion and delivery of the gas) is

$$\text{H.P.}_{is} = \frac{144 \times P_1 \times \text{F.A.D.}}{33{,}000} \log_e P_2/P_1.$$

Where F.A.D. is the volume flow of air at initial conditions of P_1 and T_1 in cub. ft. per min. with P in lbs. per sq. in. abs.

This equation can be used for determining the air horsepower for water-cooled compressors of two or more stages with intercoolers between stages.

Adiabatic compression and expansion.—An adiabatic change of condition is one in which no heat is added or subtracted from the gas, and during which no losses (due to friction and eddies) occur. It conforms to the equation Pv^{γ} = constant.

When = ratio of specific heats at constant pressure and volume.
= $1 \cdot 4$ for air at normal temperatures.

Pv^{γ} = constant.

$$\text{hence } \frac{P_1}{P_2} = \left(\frac{v_2}{v_1}\right)^{\gamma} = \left(\frac{T_1}{T_2}\right)^{\frac{\gamma}{\gamma - 1}}.$$

The horsepower required to compress and deliver a gas adiabatically (or the horsepower obtained by expansion and delivery) is

$$\text{H.P.}_{ad} = \frac{144 \times P_1 \times \text{F.A.D.}}{33{,}000} \cdot \frac{\gamma}{\gamma - 1}\left[\left(\frac{P_2}{P_1}\right)^{\frac{\gamma - 1}{\gamma}} - 1\right]$$

if the compression is done in several stages adiabatically with intercoolers between stages the equation becomes

$$\text{H.P.}_{ad} = \frac{144 \times P_1 \times \text{F.A.D.} \times N}{33{,}000} \cdot \frac{\gamma}{\gamma - 1}\left[\left(\frac{P_2}{P_1}\right)^{\frac{\gamma - 1}{N\gamma}} - 1\right]$$

where N is the number of stages.

In practice, however, a certain amount of heat is given out during compression, the amount depending chiefly on the cooling arrangements and the speed of rotation. In this case the index of compression is altered, hence Pv^{n} = constant
where n is less than γ

For slow speed water jacketed machines n will be approximately
$1 \cdot 2 - 1 \cdot 25$ for air

For high speed air cooled machines n will be approximately
$1 \cdot 30 - 1 \cdot 35$ for air

These values for n should be used in place of γ for practical calculations.

Other forms of horsepower equation can be deduced from those given ; the most common to the aeronautical engineer is

$$\text{H.P.} = \frac{Kp\,J.\,W.\,\Delta T}{33{,}000}$$

when Kp is the specific heat at constant pressure.
J is Joule's equivalent.
W is gas flow in lbs. per min.
ΔT is the temperature rise, *i.e.* $T_2 - T_1$

for air $Kp = 0 \cdot 24$. J = 1,400 when ΔT is in degrees centigrade.

$$\therefore \text{H.P. approx.} = \frac{W.\,\Delta T}{100}.$$

Increase of Volume of Air by Increase of Temperature.

If a volume, V_1, of air at atmospheric pressure and at $t_1°$ F. be raised to $t_2°$ F., the air being allowed to expand freely, then the volume V_2 at $t_2°$ F. will be

$$V_2 = V_1 \frac{461 + t_2°}{461 + t_1°}.$$

Example.—If volume V_1 of air at 32° ($t_1°$) be 1,000, then volume V_2 at 525° ($t_2°$) will be :

$$V_2 = 1{,}000 \frac{461 + 525}{461 + 32} = 1{,}000 \times \frac{986}{493} = 2{,}000.$$

The following table gives the increase in volume from 32° F. :—

Increase of Volume of Air by Increase of Temperature from 32° F.

Notes on Graphs and Table showing Loss in Air Mains due to Friction.

(Graphs, see pages 760 and 761; Table, see page 758.)

The use of the graphs and table enables the loss in an air main to be quickly ascertained.

They are based on a comprehensive series of tests made in South Africa.

The results obtained must be taken as approximate, as it is impossible in such a simple way to allow for differences of pipe surface, elbows, tees, valves, etc.

Case 1.

***To find discharge in cubic feet per minute*, given that the initial pressure is 100 lbs. per sq. in. and the drop in pressure through 8,000 ft. of 4-in. main is 25 lbs. per sq. in.**

The drop in pressure for 100 ft. will be 25/80, that is, 0·3125 lb. per sq. in.

From the graph it will be seen that the intersection of the lines representing a drop 0·3125 lb. per sq. in. and 12·56 sq. ins.(the area of a 4-in. pipe) gives 970 cub. ft. of free air approximately.

The mean pressure in the pipe will be (100 plus 75) divided by 2, equals 87·5 lbs. per sq. in., or, say, 102·5 lbs. per sq. in. absolute.

From the table, under the heading ' to find free air per minute,' the multiplier corresponding to 102·5 lbs. per sq. in. absolute is 1·13 approximately.

Thus the discharge will be 970 × 1·13, or 1,100 *cub. ft. of free air per minute.*

Case 2.

To find the drop in pressure and the final pressure when a main is 8 ins. diameter and 600 ft, in length and passes 4,000 cub. ft. of free air with an initial pressure of 100 lbs. per sq. in.

From the graph the intersection of the line representing 4,000 cub. ft. of free air per minute and 28·3 sq. in. area, gives a pressure drop of 0·6 lb. per sq. in. approximately for 100 ft. run, or 3·6 lbs. per sq. in. for 600 ft., the length of the main.

A first approximation of the mean pressure is (100 plus 96·4) divided by 2, equals 98·2 lbs. per sq. in. or 113·2 lbs. per sq. in. absolute.

From the table, under the heading ' to find the pressure drop,' the multiplier corresponding to 113·2 may be interpolated as 0·71 approximately.

The corrected pressure drop will be 2·56 lbs. per sq. in., and therefore *the terminal pressure will be 97·4 lbs. per sq. in.*

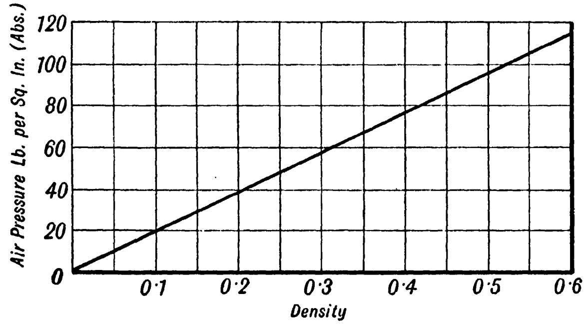

FIG. 1.

Case 3.

To find the diameter of an air main 8,000 ft. long which discharges 2,000 cub. ft. of free air per minute under an initial pressure of 200 lbs. per sq. in. and a pressure drop of 40 lbs. per sq. in. in the length of the main.

The drop in pressure per 100 ft. of main is 0·5 lb. per sq. in.

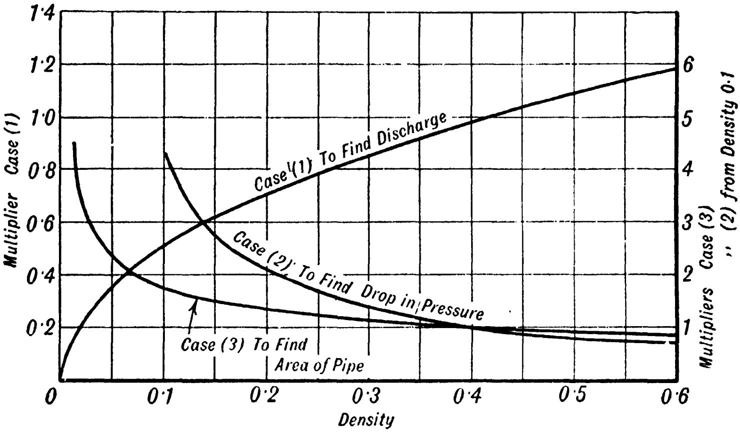

Fig. 2.

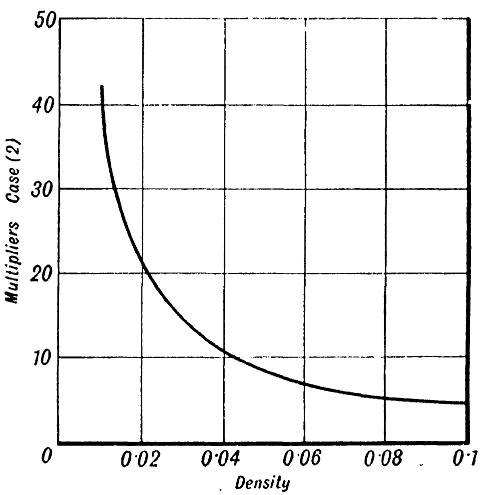

Fig. 3.

From the graph, the intersection of the lines representing 2,000 cub. ft., and a pressure drop of 0·5 lb., gives an area of 18·15 lbs. per sq. in. approximately.

From the table, under the heading 'to find area of pipe section,' the multiplier corresponding to 180 plus 15 equals 195 lbs. per sq. in. absolute is 0·70 approximately.

Hence the diameter of the main will be 0·70 × 18·15 equals 12·7 sq. ins., *so that a 4-inch main would meet the case.*

(Belliss & Morcom, Ltd.)

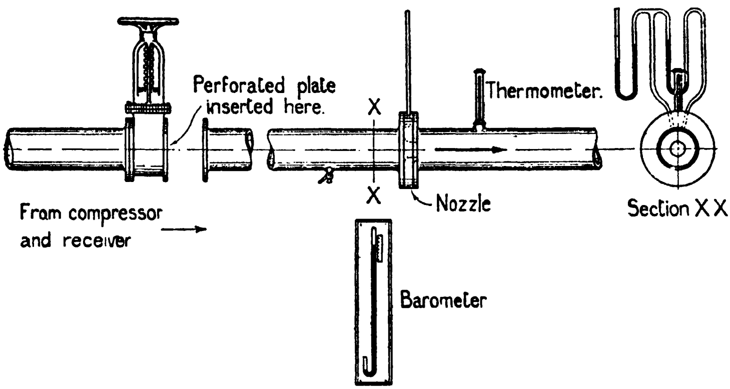
Testing of Air Compressors.

In 1929 a committee was set up by the Heat Engine Trials Standing Committee of the Institution of Civil Engineers to investigate the measurement of air flow. Resulting from the work of this committee and later from a recommendation of the British Compressed Air Society, a committee was appointed by the British Standards Institution to formulate a British Standards method of measurement of air flow and the free air delivered by compressors.

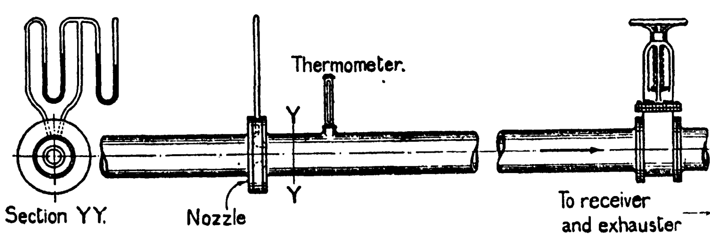
The work of this committee has resulted in the publication by the British Standards Institution of the Pamphlet No. 726–1937 which gives all the information necessary for measuring the free air delivered by an air compressor.

Definition: Free air delivered (F.A.D.). The volume of free air at the intake conditions expressed in cubic feet per minute that a compressor will take in, compress and deliver at the stated delivery pressure.

The apparatus used for testing an air compressor or alternatively an exhauster is shown in fig. 4. It consists, if testing a compressor, of a suitable pipeline leading from the compressor



Arrangement for Testing a Compressor.

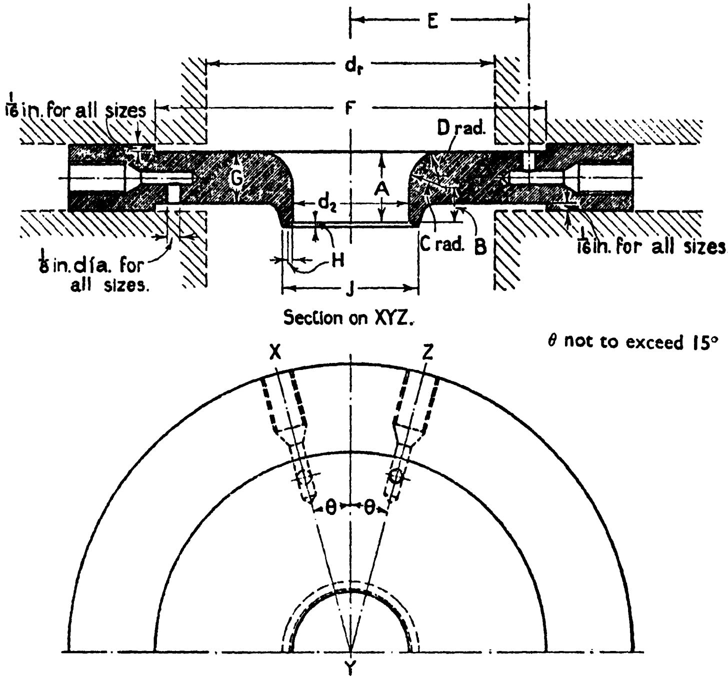


Arrangement for Testing an Exhauster.

FIG. 4.

and receiver to a straight through valve beyond which is inserted a perforated plate $\frac{1}{8}$ in. thick, having perforations $\frac{1}{8}$ in. in diameter spaced at $\frac{1}{4}$ in. centres; this plate is intended to steady the flow and is followed by the upstream pipe, the nozzle and downstream pipe, arranged as shown in fig. 4.

Fig. 5 shows the form of nozzle, size 1 in. or over. Smaller nozzles are exactly similar in the throat, but have to be modified in their general dimensions—see B.S.I. 726—1937, from which Table A is taken.



Nozzles 1-in. or Over.

FIG. 5. (See Table, p. 765.)

When testing a compressor having a steady flow, such as a turbo compressor, a receiver is unnecessary between the compressor and the measuring apparatus, but with a reciprocating machine a receiver of sufficient size must be inserted to damp out pulsations.

METHOD OF TEST.

By suitably adjusting the straight through valve immediately before the nozzle, the correct working pressure is maintained on the compressor.

The following readings are taken when making a test :—

P_i—absolute pressure at intake of compressor in inches of mercury. (Generally the atmospheric pressure prevailing at the time.)

t_i—the intake temperature in degrees Fahrenheit.

Readings taken at the measuring apparatus :—

h—pressure drop across the nozzle in inches of water. Measured by the manometer shown, fig. 4, section XX.

m_2—the absolute pressure at the downstream side of the nozzle. This is obtained by adding or subtracting from the atmospheric pressure, as given by the barometer, the water gauge reading obtained from the second leg reading of the manometer shown, fig. 4, section XX.

t—the temperature of the air in ° F. at the downstream side of the nozzle

15	36	15·000 ± 0·010	9·075 ± 0·015	4·500	4·950	3·000	± 0·010	18 7/8	38 1/4	3/4	1/2	16 1/2

* The curved surface must not depart from the nominal profile by more than this tolerance at any point between the cylindrical throat and the upstream face of the nozzle.

The dimensions given in fractions of an inch are not required to a high degree of accuracy.

Intermediate sizes of nozzles when made shall conform to intermediate tolerances and shall be proportioned on the dimensions given for the 1 in. or 10 in. nozzles

From the foregoing observations the F.A.D. is found from the formula:—

$$\text{F.A.D.} = K\,(T_i/P_i)\ \sqrt{h}\ \sqrt{m_2}/T$$

in which K = the constant for the nozzle (see Table B).

$$T_i = 459{\cdot}6 + t_i.$$

where t_i = intake temperature in ° F.

P_i = absolute pressure at intake in inches of mercury.

h = pressure drop across nozzle in inches of water.

m_2 = absolute pressure on the downstream side of the nozzle in inches of mercury.

This is obtained by adding or subtracting from the atmospheric pressure, as given by the barometer, the water-gauge reading obtained from the appropriate manometer. The water-gauge readings are converted to inches of mercury by dividing by 13·6.

$$T = 459{\cdot}6 + t$$

where t = temperature at the nozzle in ° F.

The nozzle may also be inserted in a pipe line where the pressure downstream of the nozzle is above that of the atmosphere. It is important to ensure steady flow at both upstream and downstream sides of the nozzle, and that the recommendations set out in detail in B.S.I. No. 726–1937 should be carried out.

The following table shows the standard nozzle sizes from ⅜ in. up to 15 ins., covering a range of F.A.D. from 6 cub. ft. per min. to 30,000 cub. ft. per min. Intermediate and larger nozzles can be used provided they follow the general form of fig. 4.

SANITARY ENGINEERING.

The term ' Sanitary Engineering ' is used loosely to include all engineering works designed and executed in the interests of public health. More specifically, it is applied to the sanitation of buildings. This section covers that part of sanitary engineering in the wider sense, which relates to drainage, including ' Sewerage,' ' Sewage Treatment and Disposal ' and ' Sanitation of Buildings.'

Reference to Publications.

In the following text the reader is referred to British Standard Specifications, published by The British Standards Institution, 28 Victoria Street, London, S.W. 1, thus: (B.S. 1438). These specifications give particulars of the qualities and dimensions of the materials used.

Sanitary works are carried out in accordance with Statutory Rules and Orders (S.R. & O.) and By-laws made under Acts of Parliament. The main relevant publications of these kinds are mentioned. In addition, local Acts and By-laws should be studied.

For more detailed information on sanitary engineering law, theory and practice than can be included in the present work, the reader is referred to the *revised edition* of *The Work of the Sanitary Engineer* (Macdonald & Evans, 8 John Street, Bedford Row, London, W.C. 1), from which the illustrations herein are reproduced.

Sanitary Enactments.

Legislation on sanitation was amended and largely consolidated by the *Public Health Act*, 1936, which is now the most important enactment on the law of public health. London has its own particular code in the *Public Health (London) Act*, 1936. Water supply (the law of which is a concern of the sanitary engineer), has recently received modern interpretation by the *Water Acts*, 1945, and 1948, designed ' to make provision for the conservation and use of water resources and for water supplies and for purposes connected therewith.' Other statutory provisions relating to particular aspects of sanitary administration are the *Public Health (Drainage of Trade Premises) Act*, 1937, the *Land Drainage Act*, 1930, the *River Boards Act*, 1948, and the *Rivers Pollution Prevention Acts*, 1876 and 1893. There are additional local Acts operative only in particular districts.

Under the *Public Health Act*, 1936:

' " Drain " means a drain used for the drainage of *one building* or of *any buildings* or yards of appurtenant to buildings *within the same curtilage*.'

' " Sewer " does not include a drain as above defined, but otherwise includes all sewers and drains used for the drainage of buildings and yards appurtenant to buildings.'

The above legal definitions are accepted and used by sanitary engineers as technical terminology and are so used in the following text.

SEWERAGE.

Discharge of Sewers.

The capacities of sewers can be calculated when the dimensions, hydraulic gradients and character of the internal surfaces are known: various formulæ have been evolved for this purpose of which the most accurate are the empiric formulæ based on experiments.

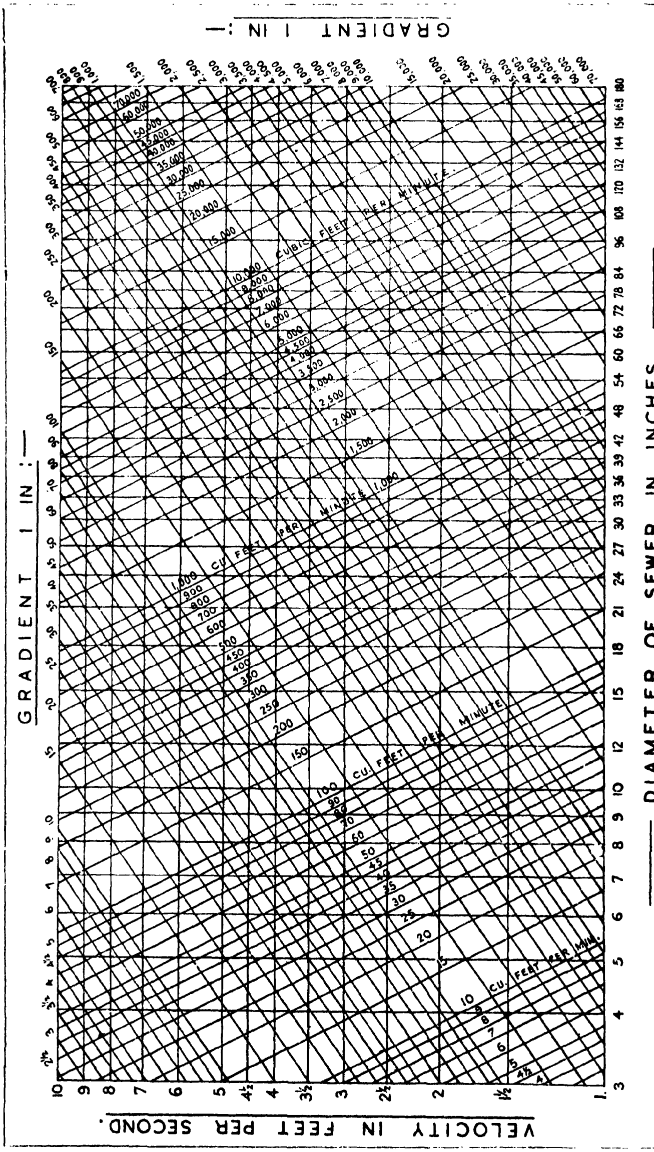

FIG. 1.—Flow in Slimy Sewers according to Barnes' Formula.—Method of using diagram: at the point of intersection of the diagonal line giving gradient and the vertical line giving diameter of pipe intersect also the diagonal line giving discharge and the horizontal line giving velocity.

For general use in determining the flows in well-used sewers of all materials, Barnes' formula 'for flow in slimy sewers' is perhaps the most accurate. It reads as follows:

$$V = 107\, m^{0\cdot7}\, i^{0\cdot5}$$

where:

V = velocity of flow in feet per second.

m = hydraulic mean depth in feet (*i.e.* the cross sectional area of flow divided by the 'wetted perimeter' of contact between the water and its bed.

i = the vertical fall divided by the length (measured along the length of the pipe, not horizontally from end to end of pipe).

Crimp and Bruges' formula is a satisfactory approximation which has been very largely used in this country. It reads as follows:

$$V = 124\, m^{0\cdot667}\, i^{0\cdot5}$$

the notation being as before. The form of Crimp and Bruges' formula that is of general use for determining the discharge of *circular pipes* is:

$$Q = \frac{3\cdot072 D^{\frac{8}{3}}}{\sqrt{I}}$$

where:

Q = discharge in cubic feet per minute.

D = diameter of pipe in inches.

I = length divided by fall.

For finding as accurately as possible the discharge of new cast-iron rising mains, Barnes' formula for flow in new asphalted cast iron pipes should be used:

$$V = 174\cdot1\, m^{0\cdot769}\, i^{0\cdot529}$$

This formula also gives a reasonable approximation for flow in steel pipes.

General Principles of Sewerage.

Apart from rising mains and inverted siphons, all sewers are designed as if they were open watercourses, the hydraulic gradient being at or below the crown line of the sewer. Thus the pipes are not considered to be surcharged and the hydraulic gradient is virtually the gradient of the crown of the sewer when the sewer is flowing full, or the gradient of the invert when there is very little flow. On this basis, sewers of different diameters connecting together are generally arranged with their crowns, not inverts, level.

The fall of the invert should be continuously in the direction of flow throughout the length of the sewer and the gradient should be sufficient to ensure a velocity of at least $2\frac{1}{2}$ ft. per second when the sewer is flowing full, in order that solids such as detritus and fæcal matter shall be swept along with the flow. Table I gives the minimum gradients for sewers flowing nearly half full at least once a day.

TABLE I.—MINIMUM GRADIENTS FOR BEST WORKING CONDITIONS IN CIRCULAR SEWERS. VELOCITY OF FLOW $2\frac{1}{2}$ FEET PER SECOND.

Diameter of Sewer (Ins.)	Gradient 1 in:	Discharge (Cubic Ft. per Minute.)
6	150	29·8
7	190	40
9	265	66·1
12	385	118
15	520	184
18	660	266
21	820	360
24	970	473
27	1100	608
30	1300	740
33	1500	889
36	1650	1069
39	1850	1249
42	2050	1446
45	2250	1659

When sewers receive very little flow, the velocity of flow is less than when they are flowing full, and therefore their gradients should be increased accordingly to bring their velocities up to 2½ ft. per second. Table II gives the proportional velocities, discharges and depths in sewers flowing partly full.

TABLE II.—DISCHARGES AND VELOCITIES IN SEWERS FLOWING PARTLY FULL.

Proportional Depth.	Proportional Velocity.	Proportional Discharge.
0·05	0·257	0·005
0·10	0·401	0·021
0·15	0·517	0·049
0·20	0·615	0·088
0·25	0·701	0·137
0·30	0·776	0·196
0·35	0·843	0·263
0·40	0·902	0·337
0·45	0·951	0·417
0·50	1·000	0·500
0·55	1·031	0·586
0·60	1·072	0·672
0·65	1·099	0·756
0·70	1·120	0·837
0·75	1·134	0·912
0·80	1·140	0·977
0·85	1·137	1·030
0·90	1·124	1·066
0·95	1·095	1·075
1·00	1·000	1·000

Velocities in sewers (other than in sewers of small diameter not flowing more than fractionally full) should be kept within bounds so as to prevent scour. Generally, the velocity of flow should not exceed 10 ft. per second and preferably 6 ft. per second, unless the sewers are constructed of cast-iron or other very durable material. Table III gives the gradients at which velocity reaches 10 ft. per second.

TABLE III.—ABSOLUTE MAXIMUM GRADIENTS FOR CIRCULAR SEWERS. VELOCITY OF FLOW 10 FT. PER SECOND.

Diameter of Sewer (Ins.)	Gradient 1 in.	Discharge (Cub. Ft. per Minute.)
6	10	115
7	12	159
9	17	261
12	25	464

42	130	5743
45	145	6537

Sewerage Systems.

There are two principal systems of sewerage, known respectively as the 'combined' and the 'separate' systems. In the former, one set of sewers is provided for the removal of both the soil

sewage and also the rainwater; in the separate systems two sewers are provided in every street, one for soil sewage and the other for rainwater. Both systems have their advantages, but these are counterbalanced by certain disadvantages.

The combined system has the advantage of simplicity, but it involves large and deep sewers with small volumes of sewage flowing in them in dry weather; and where the sewage has to be pumped and purified this system produces a larger volume of sewage than the separate system.

On the other hand, a separate system of sewers becomes very complicated, especially in large towns, and there is a great risk of soil drains being connected to the surface water sewers. The latter discharge direct into the nearest river or stream, and can therefore be made of smaller size than in the combined sewerage system, which concentrates all liquid upon one point. The drainage of all streets and yards is taken direct into the surface water sewers.

There is also the 'partially separate' system, in which the greater part of the rainwater is passed to surface water sewers but the run-off from back roofs and yards is permitted to be discharged to the soil sewers.

Soil Sewerage.

The quantity of sewage discharged from a built-up area is approximately the water supply to that area plus infiltration of subsoil water to leaky sewers and drains. For the design of new soil sewerage systems it suffices to ascertain or estimate the water demand of the area, in gallons per head of population per day, and make the sewers capable of taking at least four, but nor more than six, times the flows so estimated. Generally, the water demands can be obtained from the water authority. Otherwise, they may be taken as being as follows:

Small villages	10–15 gallons per head per day.
Medium to small provincial towns	20–30 ,, ,, ,, ,, ,,
Large towns	30 gallons per head per day and upwards.

The water demand plus the dry-weather infiltration is known as the 'dry-weather flow.'

The water demand and the flow of sewage vary throughout the day, being about twice the average rate of flow round about midday, and being approximately nil in the early hours of the morning. There are also daily variations: on Mondays and Tuesdays, the flow is above the average, for these are washing days; on Sundays the flow is low. The figure of four times dry-weather flow makes allowance for all these variations, plus a moderate amount of infiltration water. A large factor of safety, up to six times dry-weather flow, is desirable when infiltration is known to be high or where future extensions of the system cannot be accurately estimated.

The method of estimating the flow in any particular sewer is to count the number of houses, multiply this by the number of persons per house and by the number of gallons per head per day dry-weather flow. The total dry-weather flow so obtained is multiplied by four or six, as the case may be.

The number of persons per house may be obtained from the local authority, or otherwise estimated on averages. Prior to 1938, the number of persons per house had been falling from 5 to about 4, or 3·7 in the outer London suburbs, and 3 in some housing estates. At present the figure is higher, owing to the shortage of houses.

Surface-water Sewerage.

The flows in separate surface water sewers are considered to consist purely of rainwater; the flows in combined sewers include soil sewage, but during storm time the flow of soil sewage is so small compared with the rainfall run-off that it can be neglected. In the above respect, partially separate systems are dealt with on their own merits.

The Lloyd-Davies method of designing surface water sewers is now generally accepted. In the recognised application of this method, the sewer in question is designed to take the run-off from the drainage area resulting from a storm which is considered to produce the greatest momentary run-off that can occur once a year. Heavier storms are considered to be accommodated by surcharge of sewers, and exceptionally heavy storms of rare occurrence are permitted to cause flooding, on the grounds that the damage done does not justify the construction of extremely large sewers capable of taking any flow likely to occur.

Storms of short duration are more intense than storms of longer duration. The more intense a storm is, the less frequently does it occur. The statistics of short storms of high intensity in Great Britain are expressed by Bilham's formula, as follows:—

$$N = 1 \cdot 25t(r + 0 \cdot 1)^{-3 \cdot 55}$$

where:

N = number of occurrences of storms of this intensity in 10 years.
t = time of duration in hours.
r = rainfall in inches during t.

The storm which produces the greatest run-off from any drainage area is that which has a duration equal to the 'time of concentration,' the time of concentration being the time taken for the water to run from the most distant part of the drainage area to the point at which the flow is desired to be known. This time of concentration is calculated by finding the velocity of flow

through each component length of the main sewer and multiplying by the length. To this is added a 'time of entry' of about 3 minutes, to allow for water to run over roofs and ground and find its way to the sewers.

For many years a rough estimate of the intensity of rainfall was made by use of the Ministry of Health formulæ, as follows:—

$$R = \frac{30}{t + 10}$$ for storms of duration varying from 5 to 20 minutes.

$$R = \frac{40}{t + 20}$$ for storms of duration varying from 20 to 100 minutes.

where:

R = inches of rainfall per hour.

t = duration of storm in minutes.

These formulæ are limited in application and are not strictly accurate, and the figures given in Table IV are recommended for determining the intensities of storms for the purposes of surface-water sewer design.

TABLE IV.—INTENSITIES OF STORMS FOR SEWER DESIGN PURPOSES.

Duration of Storm in Minutes.	Rainfall Intensity in Inches per Hour.	Duration of Storm in Minutes.	Rainfall Intensity in Inches per Hour.

37	0·62	570	0·11
38	0·61	660	0·10
39	0·60	780	0·09
40	0·59	950	0·08
42	0·57	1150	0·07
44	0·56	1500	0·06
46	0·54		

The impervious area is found as follows. Firstly, the impermeability factor of the area is determined by measuring the roof and paved areas of a sample area and multiplying these by impermeability factors for each type of surface, as given in Table V.

TABLE V.—IMPERMEABILITY OF SURFACES.

Type of Surface.	Impermeability Factor.
Watertight roof surfaces	0·70 to 0·95
Asphalt and other dense pavements in good order	0·85 to 0·90
Stone, brick and wood-block pavements with tightly cemented joints	0·75 to 0·85
Stone, brick and wood-block pavements with open or uncemented joints	0·40 to 0·70
Cobblestone pavements	0·40 to 0·50
Macadam roadways	0·25 to 0·60
Gravel roads and walks	0·15 to 0·30
Parks and open spaces, lawns, meadows, etc.	0·05 to 0·30
Wooded areas	0·01 to 0·20

Thus, the impermeability factor for the drainage area can be found, and this, multiplied by the gross acreage, gives the 'impervious area' in acres.

The run-off from the drainage area can then be found by the Lloyd-Davies formula, as follows:

$$Q = 60 \cdot 5 \times Ap \times R$$

where:

Q = cubic feet per minute run-off from area.
Ap = impervious area, or gross area in acres multiplied by impermeability factor.
R = inches of rainfall per hour.

The Lloyd-Davies method is essentially one of trial and error for, until the diameter of sewer has been decided, the velocity of flow cannot be known; until the velocity of flow is known the time of concentration cannot be known; until the time of concentration is known the intensity of rainfall cannot be known and the diameter of sewer cannot be calculated. The designer therefore selects a size of sewer, calculates the run-off according to the Lloyd-Davies formula, selects a new size of sewer, and so on, until the appropriate size has been found.

The calculation is made for each small component area of the total drainage area so as to determine the sizes of the branch sewers. But the flows in the main sewers are not the total flows of the branch sewers so determined, and must be calculated afresh, because the main sewers are influenced by longer times of concentration, and therefore the applicable rainfall intensities are smaller.

The above is the outline of the Lloyd-Davies method. To this have been added considerable elaborations of theory to make allowance for irregular distribution of impervious area.

Soakaway Systems for Surface Water.

Where the subsoil is permeable, roof water is discharged to soakaways, and in such areas water from road surfaces may also be soaked away provided there are no particular risks to water supplies. If, owing to the use of soakaways for all surface-water, it is desired to exclude surface-water from the soil sewers, a 'nominal' surface-water sewer must be provided, otherwise property owners have the right to discharge surface-water to the soil sewers. The method adopted in such circumstances is to construct soakaways under the road at intervals of about 300 ft. and to connect them by 6-in. diameter linking sewers to which are connected gullies. These linking sewers also serve as overflows in the event of any soakaway becoming surcharged. An extra-large soakaway is constructed at the lowest point on every linked system of soakaways.

Soakaways consist of circular chambers corbelled in at the top or covered with slabs and provided with heavy manhole covers. The walls are of 9-in. open-steined brickwork; or else of alternate rings of four courses of brickwork in header bond in cement mortar and four courses of dry brickwork in header bond, the vertical joints being kept open with pebbles. The walls are given foundations of concrete, but generally the floors are not paved.

Soakaways should not be filled in with rubble or other material, as this robs them of storage capacity. The storage capacity usually allowed is the equivalent of ½-in. of rainfall over the impervious area drained. Any storage below the natural level of the subsoil water is not included.

Ventilation of Sewers.

Sewers are ventilated for the purposes of relieving air-pressure so as to permit free flow of sewage and to prevent the breaking of the seal of traps on the fittings in buildings. Ventilation is provided also to remove dangerous or objectionable gases or vapours.

The gases found in sewers are partly the results of decomposition and include methane (which is explosive) and hydrogen sulphide (which is very poisonous and which also attacks Portland cement). Petrol vapour, due to petrol finding its way to the sewers from roads and garages, or even from private houses, is not only explosive but poisonous. Coal gas and dangerous gases from the subsoil can also find their way to the sewers.

The means of obviating all these dangers are :

(1) Designing sewers to self-cleansing gradients so that sludge does not settle and methane and hydrogen sulphide are not formed by the decomposition of septic sediment.

(2) Control to prevent discharge of petrol, etc., to the sewers. (This includes enforcing of the provision of petrol interceptors at garages and the control or discharge of trade effluents.)

(3) The use of full safety precautions by men entering sewers. See Ministry of Health publication : *Accidents in Sewers : Report on the Precautions Necessary for the Safety of Persons entering Sewers and Sewage Tanks.*

(4) Adequate ventilation to remove any gases or vapours which may have collected.

In areas where the local authorities do not require intercepting traps between the drains of premises and the sewers, the sewers are very adequately ventilated by the stack-pipes at the heads of all soil drains, and therefore no other ventilation is necessary. Where interceptors are used, the drainage systems to premises are ventilated between fresh-air-inlets and stack-pipes, but the sewers, being isolated by the traps, need additional ventilation. This is usually provided by ventilating columns placed at the heads of all branch sewers and at key points or main intersections on the sewerage system. Such columns should be carried to well above eaves level of nearby buildings. Ventilation is given by ventilating manhole covers also, where these can be used without causing nuisance.

The direction of flow of air in sewers cannot be predicted because it is mostly due to local differences of barometric pressure and the wind : theoretically it is not in the same direction as the wind. Less important causes of air flow are the ebb and flow of the sewage displacing air, the drag of the sewage flowing downhill and the tendency for warm moist air to flow up the gradient.

Flushing of Sewers.

The top ends of branch sewers generally receive little flow and therefore some provision should be made for flushing them. An economical arrangement is to provide a disc-valve in the manhole at the head of every branch sewer in order that the manhole may be filled with water from a tank vehicle or hydrant to a mark on the side of the manhole and the water released by opening the valve.

When sewers are unavoidably laid at inadequate gradients at which it is expected that silting will take place, or when inverted siphons are constructed, flushing tanks should be installed. An automatic flushing tank consists of a storage tank incorporating a flushing siphon which discharges to the nearest manhole. Water is delivered to a separate chamber isolated from the flushing tank by a trap. Company's water is metered and the flow regulated by a bib-tap or needle valve. An arrangement should be made for air to find its way to the flushing tank, otherwise the siphon will not function properly.

A suitable capacity of flushing tank is one-tenth of the total cubic capacity of the length of sewer to be flushed.

Construction of Sewers.

Small diameter sewers are constructed of salt glazed ware pipes (B.S. 65) ; salt glazed glass (vitreous) enamelled fireclay pipes (B.S. 540), the last being more commonly used in the North of England and in Scotland ; concrete pipes, reinforced or otherwise, with socketted joints or ogee joints (B.S. 556) ; cast-iron pipes (B.S. 78) ; and spun cast-iron pipes (B.S. 1211).

Stoneware and fireclay pipes are used for the majority of small diameter sewers : concrete pipes are less expensive for diameters of about 12 ins. upwards. Cast-iron pipes are used for rising mains, siphons, or for sewers laid in bad ground, or as an alternative to stoneware or concrete pipes surrounded with concrete.

The following are the normal minimum requirements of the Ministry of Health as regards concrete protection of salt glazed ware, fireclay or concrete pipes (numbered as on Ministry of Health Form K29) :

'(2) All pipes and tubes in heading or with 20 ft. or more of cover in trenches to be surrounded with at least 6 ins. of concrete.

'(3) Subject to (2) all pipes and tubes with over 14 ft. of cover to be bedded on and haunched with at least 6 ins. of concrete to at least the horizontal diameter of the pipe or tube. Any splaying of the concrete to be above that level.

'(4) Subject to (2) all pipes and tubes of 18 ins. diameter and over to be bedded on and haunched with at least 6 ins. of concrete to at least the horizontal diameter of the pipe or tube. Any splaying of the concrete to be above that level.

'(5) Subject to (6) all pipes and tubes under 18 ins. in diameter and with less than 14 ft. of cover may be laid without concrete, if the joints are of the socket or collar type (but concrete tubes with OG joints are permissible when laid as in (2), (3), (4) or (6).

'(6) All pipes and tubes with less than 4 ft. of cover under roads, or 3 ft. not under roads, to be surrounded with at least 6 ins. of concrete.'

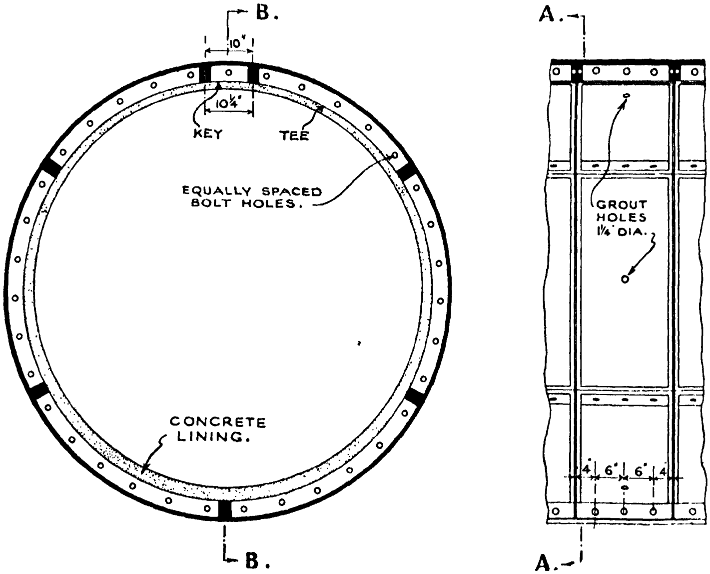

FIG. 2.—Cross and Longitudinal Sections of Cast-iron Segmental Sewer.

Sewers of large diameter are constructed of concrete pipes, mass concrete, mass concrete lined with brickwork, reinforced concrete, brickwork (special radial bricks sometimes being used), cast-iron pipes, bolted cast-iron segments, bolted pre-cast concrete segments and other special forms of construction. The circular cross-section is generally preferred for all sizes and types of sewer except very large sewers involving the use of brickwork, when special shapes such as culverts with vertical sides and arched crowns and inverts, horse-shoe shaped culverts, U-shaped culverts and other forms are preferred, either for their hydraulic properties or for ease of construction.

Limiting Diameters.

Model Byelaws do not permit private sewers to have diameters of less than 6 ins. and public sewers are never smaller. Sewers are seldom made much larger than 10 ft. diameter, it being usual to lay two or more in parallel when a 10-ft. diameter sewer is inadequate to take the flow.

Manholes.

The Ministry of Health requires that manholes shall be provided at all changes of gradient and direction of sewers of small diameter, and at distances apart not exceeding 120 yds. Model

Byelaws require that manholes on private sewers shall not be more than 100 yds. apart. Between manholes all small diameter sewers—*i.e.* less than 30 ins. diameter—must be laid in straight lines and at even gradients. Larger diameter sewers may be laid to curves between manholes, and manholes are sometimes spaced at longer intervals, *e.g.* 500 ft., but it is good practice to maintain intervals of not exceeding 360 ft. regardless of diameter.

Manholes are means of access to small diameter sewers for rodding purposes and for entering large sewers. The chamber of a manhole on a small sewer should not be less than 4 ft. 6 ins. long by 3 ft. wide (or 3 ft. 6 ins. diameter) and 6 ft. high from the top of the benching, except where headroom is restricted by depth below ground level. The invert of the manhole should be shaped to the invert of the sewer, the sides of the channel brought up vertically to the level of the crown

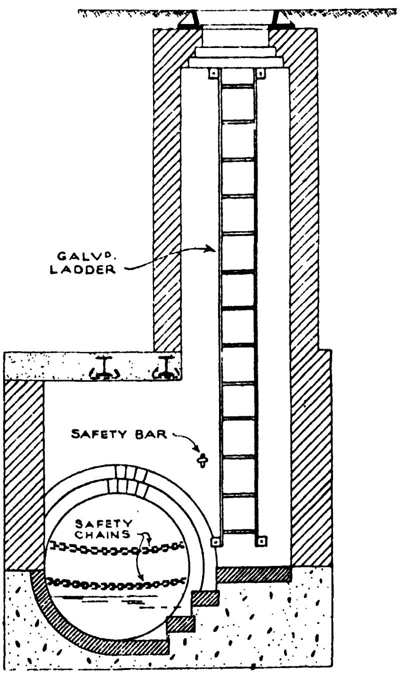

FIG. 3.—Side-entrance Manhole.

of the outgoing sewer, from which point they should turn over sharply to form the benchings. The benchings should slope evenly at about 1 in 6 towards the channels. The chambers of deep manholes should be approached by vertical shafts, the measurements of which should be 2 ft. 3 ins. by 2 ft. 7½ ins., the last measurement being taken from the face of the wall on which is fixed the ladder (or step-irons). Covers should have clear openings of not less than 20 ins. diameter.

Manholes on large sewers should be 'side-entrance' manholes, *i.e.* they should not lead directly down into the sewer but should terminate at a platform to one side of the sewer, the invert of the sewer being approached by a flight of steps or in some similar manner.

Manholes are structures which are inherently strong, and are very frequently designed extravagantly. Table VII gives the adequate thickness of manhole walls according to length of the longest wall and depth below ground or water level.

SEWAGE TREATMENT AND DISPOSAL.

Strength of Sewage.

The strength of sewage is estimated by chemical tests, but there is no test yet devised which gives an absolutely reliable and accurate indication of the difficulty of treatment. The accepted formulæ for determining strength of sewage are given in the Ministry of Health publication, *Methods of Chemical Analysis as Applied to Sewage and Sewage Effluents*, and are known as McGowan's formulæ. The index of strength as calculated by these formulæ is known as 'strength (McGowan).' The following is a quotation from the above mentioned publication.

'A good approximation can be arrived at for domestic sewage* by estimating the ammoniacal and albuminoid or organic nitrogen and the "oxygen absorbed" from $\frac{N}{8}$ permanganate in 4 hours at 27° C. and then applying the following formula to the figures so obtained:

For sewages:

(Ammon. + Organic N) × 4·5 + (Ox. abs. in 4 hours × 6·5 †).

For septic tank liquors:

(Ammon. + Organic N) × 4·5 + (Ox. abs. in 4 hours × 6·5 †).

For precipitation liquors:

(Ammon. + Organic N) × 4·5 + (Ox. abs. in 4 hours × 6·0 †).

'The subject is dealt with in the Fifth Report of the Royal Commission on Sewage Disposal Appendix IV, p. 1, *et seq.* (1910) (Cd. 4282), to which the reader is referred.'

Other than in Great Britain, and of recent years in Great Britain also, the strength of sewage has been estimated in terms of the five days bio-chemical oxygen demand (or five days B.O.D. value). This is found by determining the quantity of oxygen absorbed when sewage or sewage effluent is diluted with water containing oxygen and incubated at a constant temperature for five days.

There is no direct correlation between strength (McGowan) and B.O.D. value, for although, on the average, B.O.D. value increases in direct proportion to strength (McGowan), individual samples of various sewages show marked differences.

The Royal Commission described a sewage having a strength (McGowan) of 100 as being a medium strength sewage. A typical analysis of such a sewage is as follows:

Ammoniacal Nitrogen	3·53 parts per 100,000.
Albuminoid ,, ...	0·91 ,, ,, ,,
Total organic ,, ...	2·25 ,, ,, ,,
Oxidised ,, ...	trace
Total ,, ...	5·85 ,, ,, ,,
Oxygen absorbed at 27° C. (80° F.) in 4 hours . .	11·27 ,, ,, ,,
Chlorine	9·16 ,, ,, ,,
Solids in suspension	29·40 ,, ,, ,,

A sewage of medium strength probably has, on the average, a B.O.D. value of 35 parts per 100,000, or slightly less.

'* Apart from cases where large volumes of trade wastes, containing *e.g.* starch, glucose, or gas liquor, are present.

'† *Note.*—When N/80 permanganate has been used in the "oxygen absorbed test," this figure would have to be further multiplied by 1·6, in order to give an approximately correct result.'

The strength of sewage varies throughout the day, being at a maximum at about the same time as the maximum rate of flow, *i.e.* at about midday, and being weakest during the night. When samples are taken for the purpose of determining strength, as a prelude to design, they must

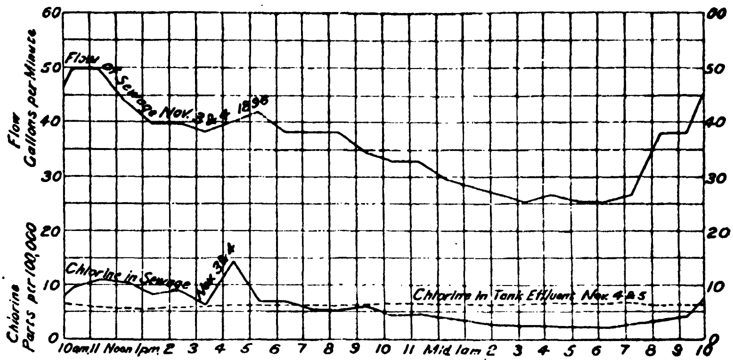

FIG. 4.—Typical Curves showing Variation of Rate of Flow and Strength of Sewage throughout the day.

be taken at regular intervals over twenty-four hours, the size of each sample being in proportion to the rate of flow at the time. The component samples are then thoroughly mixed to form the final sample for analysis.

Standards of Treated Effluents.

In 1913 the Royal Commission issued their 8th Report, in which they summarised their conclusions as follows :

(*a*) The law should be altered so that a person discharging sewage matter into a stream shall not be deemed to have committed an offence under the Rivers Pollution Prevention Act, 1876, if the sewage matter is discharged in a form which satisfies the requirements of the prescribed standard.

(*b*) The standard should be either the general standard or a special standard which will be higher or lower than the general standard as local circumstances require or permit.

(*c*) An effluent in order to comply with the general standard must not contain as discharged more than 3 parts per 100,000 of suspended matter, and with its suspended matters included must not take up at 65° F. (18·3° C.) more than 2·0 parts per 100,000 of dissolved oxygen in five days. This general standard should be prescribed either by Statute or by Order of the Central Authority, and should be subject to modifications by that Authority after an interval of not less than ten years.

(*d*) In fixing any special standard the dilution afforded by the stream is the chief factor to be considered. If the dilution is very low it may be necessary for the Central Authority, either of their own initiative or on application by the Rivers Board, to prescribe a specially stringent standard, which should also remain in force for a period of not less than ten years.

(*e*) If the dilution is very great the standard may, with the approval of the Central Authority, be relaxed or suspended altogether. Our experience leads us to think that as a general rule, if the dilution, while not falling below 150 volumes, does not exceed 300, the dissolved oxygen absorption test may be omitted and the standard for suspended solids fixed at 6 parts per 100,000. To comply with this test no treatment beyond chemical precipitation would ordinarily be needed. If the dilution, while not falling below 300 volumes, does not exceed 500, the standard for suspended solids may be further relaxed to 15 parts per 100,000. For this purpose tank treatment without chemicals would generally suffice if the tanks were properly worked and regularly cleansed. These relaxed standards should be subject to revision at periods to be fixed by the Central Authority, and the periods should be shorter than those prescribed for the general or for the more stringent standards.

(*f*) With a dilution of over 500 volumes all tests might be dispensed with, and crude sewage discharged, subject to such conditions as to the provision of screens or detritus tanks as might appear necessary to the Central Authority.

The standards mentioned in (*e*) and (*f*) are not intended to apply to effluents discharged into streams which are used for drinking water or to streams the water of which, at the point of discharge of the sewage effluent, normally takes up more than 0·2 parts per 100,000 of dissolved oxygen in five days at 60° F. Up to the present time the proposals contained in the Report have not been embodied in any Act of Parliament, and have therefore no official authority, and must be treated as suggestions only.

Quantity of Sewage to be Treated: Separation and Treatment of Storm Water.

Present-day practice is to allow for full treatment of all sewage arriving at the works up to three times dry-weather flow. This applies to the sewage from both separate and combined sewers.

At works treating sewage from combined or partially separate sewerage systems, any flow in excess of three times dry-weather flow is passed to stand-by or storm tanks, where it is settled and stored until such time as, the rate of flow having reduced, the stored sewage can be passed through the works for full treatment. If the quantity of storm water exceeds the capacity of the storm tanks, the storm tanks function as sedimentation tanks and the settled effluent is passed to the outfall without further treatment, or with such treatment, *e.g.* treatment on land, as can be given without undue expense.

Storm tanks normally have a capacity of six hours dry-weather flow and receive the flow from separation weirs, which are placed below the screens and detritus tanks but come before the remainder of the treatment works. The tanks are usually in the form of long flat-bottomed rectangular sedimentation tanks, with weirs at the outlet ends, protected by floating scumboards, and floating arms (also protected by floating scumboards), for the decanting of the tank contents after a storm. Sludge is removed by sweeping to the sludge outlets, either manually or mechanically.

At sewage treatment works which derive their flows from separate systems from which little storm or infiltration water is expected, storm tanks are usually omitted, the whole of the flow arriving at the works being separated after the sedimentation tanks, or passed through the entire works.

Storm overflows for the discharge of crude sewage without treatment of any kind are not permitted at sewage treatment works: once the sewage has arrived at the treatment works, it must be given treatment at least by settlement in storm tanks or the sedimentation tanks.

General Outline of Treatment.

The purpose of sewage treatment is to remove as much as possible of the organic matter from the sewage and to oxidise the remainder, converting it into inorganic matter in order that it does not putrefy, causing a nuisance, or deplete the watercourse, into which it is discharged, of oxygen, thereby destroying fish life. The process of sewage treatment, therefore, consists of the mechanical removal of suspended solids and the oxidising of dissolved solids, with the aid of bacteria and other organisms.

Sewage treatment works normally consist of:

1. Screens.
2. Detritus tanks or channels.
3. Sedimentation tanks.
4. The aeration unit (land treatment, percolating filter treatment or activated sludge treatment).
5. Humus tanks (following percolating filter treatment), or final sedimentation tanks (following activated sludge treatment).

In addition, there are ancillary works, including plant for treating and disposing of the sludge that has been collected in the sedimentation tanks.

Formerly, the design of sewage treatment works and the determination of the proportions of the component units were (in Great Britain) almost entirely based on the recommendations on the Royal Commission on Sewage Disposal and on various figures, other than recommendations, which appeared in the Reports or the Appendices thereto and which, it was believed with or without justification, were the specific requirements of the Ministry of Health. Thus, for many years design became stereotyped and little progress was made. Now, under the influence of American and German practice, etc., and as a result of extensive research, practice has changed considerably and only in part remains the same as in the days of the Royal Commission. The following description of works, and methods of determining capacities, are in accordance with advanced but sound current practice.

Screens.

Opinion on screens varies considerably. Some authorities prefer to use screens with ½- to ¾-inch clear spaces so as to remove as much as possible of the larger organic material before further treatment of the sewage. Others install screens with wide spaces sufficient only for the purpose of protecting pipe-lines and pumping plant from large solids. Sometimes screens are omitted. At some works, screenings are removed by fine screens and, after maceration, returned to the flow of sewage. As an alternative to this process, 'Comminutors' which combine the offices of screen and macerator may be installed.

At small works hand-raked screens are most suitable. These should be set at an angle and so arranged that the screenings may be raked upwards into a rolled steel channel from which they may be shovelled or swept into barrows. At large works, *i.e.* those serving more than 20,000 persons, mechanical screens (of many designs) are installed. The submerged area of a hand-raked screen should not be less than 1½ ft. super per thousand head of population. The sizes of mechanically raked screens should be such that, at the maximum rate of flow, the velocity through the bars is in the region of 1½ ft. per second.

When screenings are not disintegrated and returned to the sewage, they may be passed to sludge digestion tanks (if provided), discharged to trenches and covered with earth, discharged with the sewage sludge, or destroyed by incineration.

Detritus Tanks and Channels.

Detritus tanks are provided for the purpose of removing heavy inorganic sediment such as road grit, gravel and chippings which, if permitted to pass to the sedimentation tanks, might pack and interfere with sludging. Detritus tanks were of more importance in the days of water-bound macadam roads and the prevalence of combined systems of sewerage. At the present time it is considered that they are not necessary at works treating purely domestic sewage from separate systems, although at small works they are still installed mainly for the purpose of housing and operating hand-raked screens. At all large works the installation of detritus tanks is usual. They are a necessity when sewage from combined systems or industrial areas is to be treated.

At one time the orthodox practice in Great Britain was to provide detritus tanks not fewer than two in number and having a total capacity of $\frac{1}{10}$th dry-weather-flow. These were crude pits or chambers arranged for decanting of top water and sludging. They were very unsatisfactory, being too large and therefore settling large quantities of organic material with the inorganic detritus, which often led to offensive conditions. Under the influence of American practice, various forms of constant velocity detritus channels have come to be favoured and will probably replace the simple detritus tank at all except those small works where the detritus tank serves as screen chamber and its size is mainly determined by the proportions of the screen.

The constant velocity detritus channel is based on the principle that at a velocity of flow of 1 ft. per second, comparatively fine siliceous grit will settle and remain settled, while organic particles both large and small are swept along by the current.

The means by which a constant velocity can be maintained are:

1. Manual or automatic-electric control in order that the number of channels in use can be varied in almost direct proportion to rate of flow.
2. Control of depth of flow by a flume or weir at the outlet ends of channels, and specially proportioning the cross-sections of the detritus channels in order that the velocity of flow therein remains constant at all depths of flow.
3. A combination of the above methods.

A much favoured form of constant velocity detritus channel is the channel of parabolic section, the flow through which is controlled by a rectangular standing-wave flume the invert of which is level with the invert of the channel.

The discharge of a rectangular standing-wave flume is approximately according to the formula:

$$\text{Cubic feet per second} = 3 \cdot 09\ B.H.^{\frac{3}{2}}$$

where:

B = width of flume in feet.
H = depth from invert of flume to upstream top water level, in feet.

The width at any point above the invert of the detritus channel is given by the formula:

$$X = \frac{3Q}{2H}$$

where:

X = width of channel at water level in feet.
H = depth of flow in feet.
Q = rate of flow at that depth in cubic feet per second.

In order that the grit may have time to settle the channels should not be short, and preferably the length of each channel should not be less than thirty times the maximum working depth.

At large works, grit can be removed by travelling grit pump or by mechanical dredger. At small works, the channel to be cleansed is allowed to run dry and is then dug out manually. No fewer than two channels should be provided and, generally, each channel should be controlled by its own standing wave flume or weir.

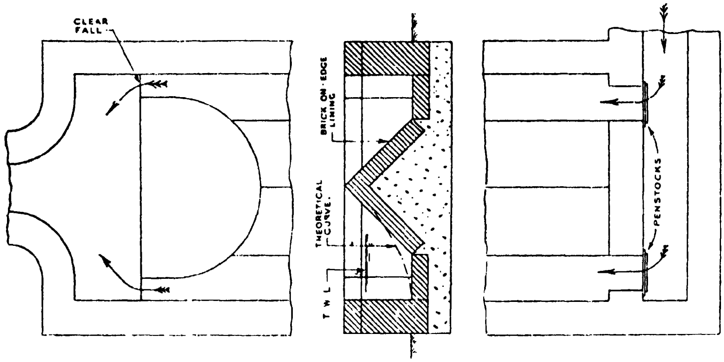

FIG. 5.—Plan and Cross-section of Constant Velocity Detritus Channel for Small Sewage-works.

Quiescent Sedimentation.

Formerly, quiescent sedimentation tanks were largely used. These were worked on the fill-and-draw principle: a tank was filled with sewage, allowed to stand for a sufficient period for settlement, the top water then decanted with the aid of a floating arm, after which the sludge was swept out manually. For this purpose, not fewer than four, and preferably eight tanks were provided, the total capacity of the battery being in the region of 16 hours' dry-weather flow. Now, continuous flow sedimentation, in which the sewage flows continuously through the tanks, is always provided. Quiescent tanks were identical, in design, with storm tanks, as described above.

Continuous Flow Sedimentation.

The detail design of sedimentation tanks is far more important than their capacities. The latter can be varied over a very wide range without causing an excessive difference of efficiency. At a time when English sedimentation tanks were being made to capacities of 10 to 15 (or even more) hours' dry-weather flow, American designers were content with capacities of 1½ to 2 hours' dry-weather flow and were obtaining satisfactory results.

At the present time those English designers who still design in terms of capacity allow 6 or 8 hours' dry-weather flow in many instances. But it is becoming appreciated that the design of sedimentation tanks is not a matter of fixing a storage capacity for retention period, but the proper design of the tank and its components for convenient and efficient operation.

The efficiency of a sedimentation tank is mostly dependent on the design of inlets and outlets. The inlet should be such that it does not produce a jet or swirling action, or set up eddies: the sewage should enter the tank quietly and at a low velocity, and any turbulence should be dissipated in a stilling-chamber. The outlets of all sedimentation tanks should be weirs of such length that the flow over them is very shallow. These weirs should be protected by scumboards which should, however, be placed sufficiently far from them not to cause a local upward velocity.

The capacity of a sedimentation tank has, however, some effect on efficiency, the latter varying more or less in direct proportion to the fourth or fifth root of the former. Of more importance is the surface area, which generally should be not less than 1 ft. super for every 300 gallons dry-weather flow, and preferably 50 per cent. greater, according to current practice.

The types of sedimentation tanks in use include:

1. Rectangular longitudinal flow tanks, 5 or more feet deep and about five times as long as they are wide. These are usually mechanically swept.

2. Pyramidal bottomed tanks with peripheral weirs and central inlets (the bottoms sloping at about 60° to the horizontal), sludged under hydrostatic head.

3. Various designs of flat-bottomed or conical-bottomed circular tanks provided with automatic sludging gear.

Pyramidal-bottomed tanks are very largely used at works of all magnitudes. The considerations in their design are that the surface area shall be adequate and that the capacity for sludge storage shall be well below the central inlet and not occupying more than one-half the capacity of the tank. The quantity of sludge to be stored in the lower part of the tank can be taken as being 2 gallons per head of population in most instances. This is approximately one week's storage.

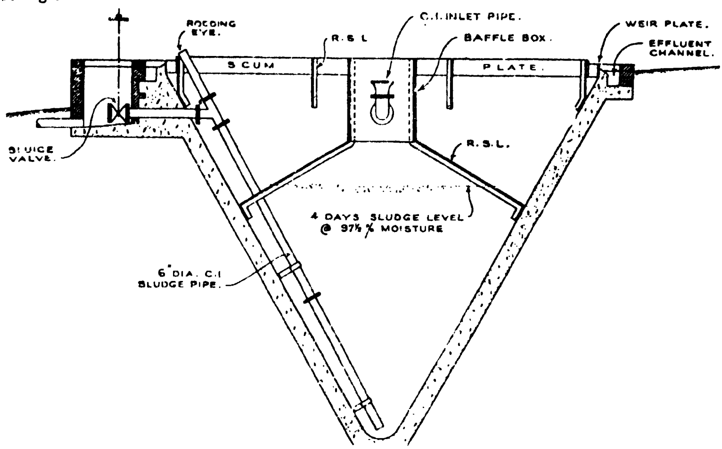

FIG. 6. –Section of Pyramidal-bottomed Sedimentation Tank.

Chemical Precipitation.

Chemical precipitation is rarely employed owing to the expense of, and difficulty in obtaining, chemicals. Generally, it is not necessary except when treating abnormal sewages.

The precipitants chiefly used are lime in a caustic state, 10 to 12 grains per gallon of sewage; lime and sulphate of iron or green copperas in the proportion of 6 grains to 3 grains of lime with 3 grains to 1 grain of copperas; lime and alumina in the proportion of 2 of the former to 1 of the latter, usually about 8 and 4 grains respectively; alumino-ferric, either with or without lime, proportion 10 to 7 grains lime and 5 to 3 grains alumino-ferric – if used without lime, up to 8½ grains per gallon.

Treatment and Disposal of Sewage Sludge.

The quantity and moisture content of the sludge settled in primary sedimentation tanks varies considerably according to the solids content of the sewage, the efficiency of sedimentation and the method of sludge removal. For design purposes it usually suffices to assume that the sludge from pyramidal-bottomed sedimentation tanks sludged under hydrostatic head amounts to ½ gallon per head of population per day and has a moisture content of 97½ per cent. and that the sludge from a mechanically swept tank amounts to ¼ gallon per head per day and has a moisture content of 95 per cent.

The methods of disposal of sludge include :—

1. Discharge into trenches and covering over, or ploughing into land.
2. Distribution by pipe-line to nearby farm land for utilisation as fertiliser.
3. Drying on drying beds.
4. Drying with the aid of filter presses or vacuum filters.
5. Heat drying.
6. Digestion followed by drying.
7. Heat treatment followed by filter pressing.
8. Incineration.
9. Dumping at sea.

Of these methods, drying on beds either of raw sludge or of sludge after digestion, is by far the most common. Sludge drying beds consist of shallow lagoons, with or without concrete floors, according to the site, and bottomed with about 9 ins. of clinker. The clinker is graded from 1 to 1½ ins. diameter of particle and topped with about 2 ins. of ¼-in. to ½-in. material. It is underdrained with agricultural tiles. One superficial yard of bed is required for every five to seven

head of population. At all works there should be four, and preferably not fewer than six individual beds, to permit rotation of the drying process. The sludge is discharged on to the beds to a depth of about 9 ins., left to dry, and removed for further drying on a dump after it has become 'spadeable.' Dried sludge has a moisture content of about 50 per cent. and weighs about 14 cwt. per cubic yard.

Sludge Digestion.

Sludge digestion has the following advantages :—

1. The quantity of sludge to be disposed is reduced.
2. The process renders the sludge inoffensive as regards odour.
3. Digested sludge usually, but not always, is dewatered more easily than raw sludge.
4. Digested sludge when dried is more useful for agricultural purposes than raw sludge.
5. The gas given off during digestion can be used for power production or for other purposes.

Sludge can be digested at day temperature, heated to a temperature of about 85° F. (mesophilic digestion), or heated to about 115° F. (thermophilic digestion). The last method is rare.

The capacities of sludge digestion tanks are as recommended in Table VIII. Two-stage digestion is generally preferred.

TABLE VIII.—CAPACITIES OF SLUDGE DIGESTION TANKS.

Type of Treatment.	Cu. Ft. Capacity per Head of Population.	
	Domestic Sewage.	Containing Trade Waste.
Single-stage digestion at day temperature .	3 to 4	6 to 8
Single-stage digestion at 85° F. . .	1½ to 2	4 to 5
Capacity of primary tank of two-stage digestion at day temperature . .	2 to 2½	3
Capacity of secondary tank of two-stage digestion at day temperature . .	1 to 1½	3
Capacity of primary tank of two-stage digestion at 85° F.	¾ to 1	2 to 2½
Capacity of secondary tank of two-stage digestion at 85° F.	¾ to 1	2 to 2½

The quantity of sludge gas that can be obtained by digestion from tanks of the above capacities varies round about 1 cu. ft. per head of population per day. The calorific value is high, *e.g.* in the region of 630 B.Th.U.'s per cu. ft. The gas can be used for power purposes, the exhaust gases from the gas engines containing usually sufficient heat to heat the sludge in the tanks. There are various methods of heating and stirring the sludge.

Closed, heated and stirred sludge digestion tanks suitable for collection of gas are manufactured by Ames Crosta Mills & Co. Ltd. and Dorr-Oliver Co. Ltd.

Sludge liquor from sludge drying beds and decanted at various levels from digestion tanks is returned to the flow of crude sewage for treatment, for it is very strong.

Land Treatment.

The clarified effluent from sedimentation tanks can be effectively oxidised by treatment on land, and this process can be economical where land is cheap and suitable for the purpose. Land treatment is, however, comparatively little used at the present time.

There are two distinct methods of using land : 'land filtration' and 'broad irrigation.' Where a suitable light friable soil can be obtained, filtration is the process adopted, the sewage passing downward through the soil to underdrains. If, on the other hand, the available land be all of a retentive character, which will not allow of the easy passage of water, the method adopted is to pass the tank effluent over the surface of the land by irrigation and to pick it up again in suitable catchwaters and reapply it to a fresh plot, and subsequently to a third or even a fourth plot before final discharge into the stream : such land should not be underdrained, or only to a very slight extent.

The quantity of liquid which can be dealt with per acre of land depends on the character of the land and the strength of the sewage.

It is not possible to make any close estimate of the amount of land required in any particular circumstances until local experience has been gained. For new installations, the recommendations given by McGowan, Houston and Kershaw in their report to the Royal Commission should be followed.

'To summarise all our results within the limits of a few sentences is impossible, but we may say in conclusion, and speaking in general terms, that we doubt whether even the most suit-

able kind of soil worked as a filtration farm should be called upon to treat more than 30,000 to 60,000 gallons per acre per 24 hours at a given time (750 to 1,500 persons per acre); or more than 10,000 to 20,000 gallons per acre per 24 hours, calculated on the total irrigable area (250 to 500 persons per acre). Further, that soil not well suited for purification purposes, worked as a surface irrigation or as a combined surface irrigation and filtration farm, should not be called upon to treat more than 5,000 to 10,000 gallons per acre per 24 hours at a given time (125 to 250 persons per acre); or more than 1,000 to 2,000 gallons per acre per 24 hours, calculated on the total irrigable area (25 to 50 persons per acre).

It is doubtful if the very worst kinds of soil are capable of dealing even with this relatively small volume of sewage. The population per acre is calculated on 40 gallons of sewage per head per day. It is here assumed that the sewage is of medium strength, and is mechanically settled before going on to the land.'

Percolating Filter Treatment.

Percolating filter treatment is by far the most common method of sewage aeration and is used at works of all sizes and for the treatment of most types of sewage. Percolating filters have replaced the contact beds which were formerly used but which are now applied, in rare circumstances only, to the treatment of trade wastes.

A percolating filter consists of a bed of clinker, broken stone, slag or other suitable medium, having a depth of, generally, not less than 4 or not more than 9 ft. The required qualities of the medium are laid down in B.S. 1438. The floor of the bed is of concrete and is usually laid to a fall of about 1 in 200 and drained with agricultural tiles: sometimes a false floor of filter tiles is laid on the true floor. On this is laid 6 or 9 ins. of large medium or stones, 4 to 6 ins. diameter, and above that the remainder of the medium. For ordinary purposes the medium should be of 1½ to 2-in. grade throughout: for high-rate filters in the region of 3-in. grade. A percolating filter is not a mechanical filter (the name is misleading) and fine material should be avoided, particularly at the surface where it would cause ponding. Filters of ' fine ' material, as described in the Reports of the Royal Commission, are now obsolete.

The tank effluent is distributed over the filter by a sparge or distributor mechanism which is usually actuated by the hydraulic head of the sewage applied to it. Most filters are circular, because this shape accommodates simple rotating distributors: large beds are rectangular and provided with travelling distributors. Tipping tray mechanisms discharging to fixed distributor channels are used for the very small percolating filters incorporated in treatment works for isolated buildings, etc.

The capacities of normal percolating filters are still determined more or less in accordance with the recommendations of the Royal Commission, except that whereas formerly it was not unusual to classify sewage as strong, medium or weak, and to allow stereotyped quantities of sewage per cubic yard according to the classification into which the sewage fell, there are now various methods of more accurately determining the amount of medium required. Of these methods, three may be recommended :—

1. Where the sewage is mainly domestic and the strength (McGowan) is known, and percolating filter treatment is preceded by continuous flow sedimentation, the capacity of the beds may be calculated in accordance with Table IX. Larger quantities of medium are required if the sewage contains inhibitory trade wastes. The quantity of sewage that can be treated per cubic yard of medium can be increased by one-third if chemical precipitation has been employed.

2. Where sewage will be mainly domestic but strength is not known, it usually suffices to allow about 0·537 cu. yds. of medium per head of population served.

3. Percolating filters have been designed in America in terms of cubic yards of medium per lb. weight of 5-days' B.O.D. per day. Lbs. B.O.D. per day is :

$$\frac{\text{Gallons per day} \times \text{B.O.D. value (pp. 100,000)}}{10{,}000}.$$

To obtain a Royal Commission effluent, 120 cu. ft. of medium should be allowed per lb. B.O.D. per day.

The above recommendations are based on the requirements that the works shall, at times, be able to treat up to three times dry-weather-flow and a ' Royal Commission effluent ' be obtained.

High Rate Filtration.

The methods of high rate filtration that have been used in this country include alternating-double-filtration, recirculation (in particular the Biofiltration process of Messrs. Dorr-Oliver Co. Ltd.), and the use of enclosed filters.

Alternating-double-filtration consists of the use of two batteries of percolating filters which are so arranged that they work in series, and the filters which are serving as primary stage of treatment can be periodically changed over with those that are serving as secondary stage. Large scale experiments have shown that filters so operated can treat (as regards B.O.D. reduction) much more sewage than normal filters. There is as yet, however, not sufficient information for it to be safe to make very definite statements as to the average capability of alternating double filtration plants compared with normal plants, but it is thought that they may be about three times as efficient.

The process of recirculation involves the return of treated effluent to the flow of untreated tank effluent, or sometimes crude sewage, in quantity equal to, or greater than, the flow of sewage. It would appear that recirculation of effluent in equal quantity to flow of sewage, using normal beds, is very effective. The Dorr process, however, includes methods of recirculation at high rates using special shallow filters and ' Clarifier ' sedimentation tanks, with the result that marked improvement of bed performance is secured.

It is claimed that the methods of alternating double filtration and recirculation involve lower horse-powers than activated sludge processes.

Enclosed percolating filters are deep filters, *i.e.* in the region of 14 ft. deep, roofed over and ventilated by electric fans, which, placed in the apex of each roof, blow downwards through the beds. Enclosed filters do not appear to be quite so efficient as alternating double filtration or recirculation filters, but they can treat twice as much sewage as ordinary percolating filters. The cost of roof construction is expensive.

Humus Tanks.

The oxidation that takes place in percolating filters is effected by bacteria and other organisms which form a slimy coating to the medium. In addition to this flora, other plant life develops, in particular growths of algæ at the surface of the beds. These growths are attacked by worms and larvæ of insects and, being broken up, are seasonally swept out of the percolating filters by the flow. The greatest quantity is noticeable in the spring, when the animal organisms recover from winter inactivity. Included with the vegetable matter are the remains of worms, larvæ, insects, together with dust washed from the medium. This material, known as humus, is collected in humus tanks before the effluent is discharged.

Humus tanks are similar to sedimentation tanks, and may be pyramidal bottomed or flat bottomed. Their surface areas and capacities are generally about half those of the sedimentation tanks for crude sewage. Scumboards are provided, because the humus tends to gas and rise to the surface if not removed shortly after settlement.

Activated Sludge Processes.

In the activated sludge processes, the bacteria which effect oxidation are not attached to particles of media as in a percolating filter, but adhere to, and combine to form, flocculi suspended in an aerated tank-effluent. The principle of activated sludge treatment involves the oxidation of

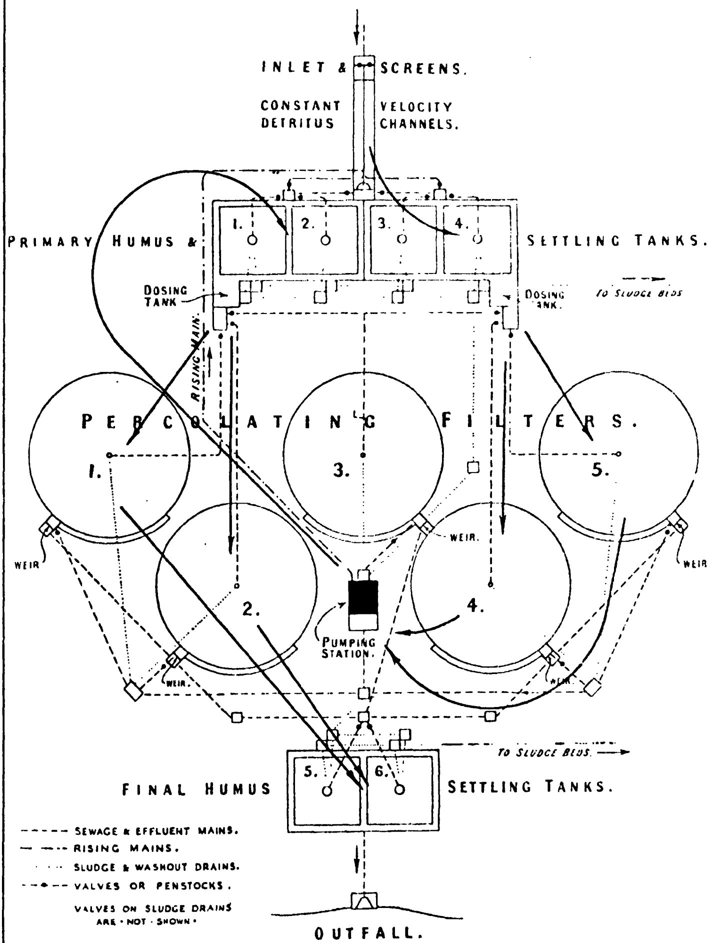

FIG. 7.—Percolating-filter Scheme capable of operation as Normal Scheme or Alternating-double-filtration Scheme.—The arrows show the direction of flow during one phase of double-filtration.

the sewage by bacteria, etc., the continued aeration of the sewage to restore the oxygen so absorbed, and the agitation of the sewage during oxidation so as to prevent the settlement of sludge and resulting local septicity.

There are two main systems of activated sludge treatment: the 'Diffused Air' system, involving the use of compressed air (the proprietary method of Activated Sludge, Ltd.); and the 'mechanical agitation' or 'surface aeration' system, in which aeration takes place at the surface. The latter system includes the 'Simplex' method (proprietary method of Ames Crosta Mills & Co. Ltd.), the Kessener process (developed by Dr. Kessener of Holland), and the Sheffield system or 'Bio-aeration' (the last is not a proprietary process).

Diffused Air System.—After close screening, and sedimentation, sometimes sufficient to remove the heaviest sludge only, the tank effluent is mingled with 'activated sludge' and passed into aeration tanks, which are sub-divided so as to form long channels about 10 to 15 ft. deep and of width equal to depth. One-tenth to one-twelfth of the floor surface of these channels consists of diffuser tiles through which compressed air is blown at a rate sufficient to oxidise the sewage and produce velocities of circulation sufficient to prevent settlement.

There are two main arrangements of diffusers: the 'ridge and furrow' system in which the floors of the channels are formed into longitudinal ridges and furrows, the diffusers being in the bottoms of the furrows; and the 'spiral flow' system in which the diffusers are placed to one side of each of the channels so as to produce a spiral rotation of the 'mixed liquor' as it flows from end to end. The quantity of air injected varies according to the strength of the sewage, the capacities of the tanks, the depths of the tanks and the conditions at the time. For design purposes, allowance should be made for the provision of 2 cu. ft. per gallon of sewage to be treated, or more if there are inhibitory trade wastes.

The capacity of aeration channels for a domestic sewage of medium strength is about 10 hours' dry-weather flow: for stronger or weaker sewages the storage capacity is increased or decreased respectively more or less in proportion to strength.

The aerated 'mixed liquor' is passed to final sedimentation tanks of capacity of not more than 6 hours' dry-weather flow, for removal of the activated sludge. This sludge is continuously withdrawn, and part is returned to the flow of sewage to form 'mixed liquor,' the surplus sludge being passed to the primary sedimentation tanks to be settled out with the crude sludge. It has been found advantageous to store activated sludge in 'reaeration channels' before returning it to the flow of sewage, and a variable number of aeration channels are reserved for this purpose. Activated sludge is recirculated at the rate of 8 to 20 per cent. of the flow of sewage.

'Simplex' System of Surface Aeration.—In the 'Simplex' system, the aeration tank is usually square on plan and has a pyramidal bottom. Aeration and circulation of the mixed liquor are effected by a screw propeller or aerating wheel which is partly submerged in the liquid at the centre of the tank. This draws mixed liquor from the bottom of the tank and sprays it over the surface. In small installations, final sedimentation tanks consist of pockets formed in the corners of the aeration tanks. In large installations the aeration tanks are arranged in series, discharging from one to anothe rand finally to a battery of sedimentation tanks. The aeration capacity is in the region of 16 hours' dry-weather flow for a sewage of average strength.

Kessener Process.—The Kessener process is similar to the 'Simplex' process in main principle, but the aeration takes place in a long channel in which spiral flow is produced by a stainless steel brush which extends the full length of each channel and, by rapid rotation, sprays the mixed liquor across the surface.

Sheffield System.—In this system sewage is made to travel at a velocity of about 1½ ft. per second through a channel about 4 ft. wide and deep, having a capacity of about 16 hours' dry-weather-flow. Part of the sewage is returned to be mingled with crude sewage at the inlet end of the channel, the remainder passes on to final sedimentation tanks for removal of the activated sludge.

The channel is folded backwards and forwards upon itself so as to occupy a small space. The motion is imparted to the mixed liquor by a series of paddle-wheels mounted on a common axle which crosses the channel in the centre of each reach. In an alternative system, paddle wheels are mounted at the bends at the ends of the component channels.

Sewage Treatment for Isolated Buildings.

The works for treating sewage from isolated buildings and from very small communities are somewhat different from other treatment works, because they have to be designed on the assumption that regular maintenance is impracticable. Works for small villages receive attention at least once or twice a week, if not every day; but plants in private ownership most often remain untouched and uninspected for weeks or even months at a time.

For the above reason, efficient continuous flow sedimentation tanks, which must be frequently sludged, cannot be used, and the septic tank, which is obsolete as regards municipal works, is substituted. Septic tanks can be sludged at very infrequent intervals of several months and give good effluents, provided that they are of adequate capacity and well designed. They are sludged by complete emptying, either to trenches or on to ploughed land, or else by cesspool-emptying

vehicles. If the last method is used, the septic tank should have a capacity that is an exact multiple of that of the local tank-vehicle. Tables X and XI give suggested capacities and proportions for septic tanks.

TABLE X.—HEAD OF POPULATION SERVED BY SEPTIC TANKS.

Periods between times of Sludging Months.	Capacity of Septic Tanks in Gallons.			
	750	1,500	2,250	3,000
6	10	20	30	40
4	15	30	45	60
3	20	40	60	80
2	30	60	90	120

TABLE XI.—PROPORTIONS OF SEPTIC TANKS.

Approx. Capacity. Gallons.	Length. Ft. In.	Breadth. Ft. In.	Depth. Ft. In.
750	7 10½	2 7½	5 9
1,500	11 3	3 9	5 9
2,250	13 10½	4 6	5 9
For 3,000 gallons capacity, use two 1,500-gallon tanks in parallel.			

The methods of treating tank effluent at these small works include percolating filter treatment and land treatment by either land filtration or broad irrigation. In addition to these, there is the controversial method of sub-irrigation. The 'Simplex' activated sludge method also has been applied to moderately small works for institutions.

The capacities of percolating filters and areas for land irrigation are generally the same as those recommended for larger works, except where there is reason to believe that the small works will be inefficient owing to some cause such as poor distribution of tank effluent over the surface of a percolating filter, or poor quality tank effluent as a result of inferior septic tank design.

Percolating filters for small works are frequently rectangular and have fixed distributor channels dosed by a tipping tray mechanism. Small rotating sparges are also obtainable. Generally, humus tanks should not be provided because, unless frequently sludged, they do more harm than good. Humus can be separated by irrigation over land.

The method of sub-irrigation is the discharge of settled effluent into a system of shallow under-drains consisting of agricultural pipes surrounded with rubble and covered with earth. Because the degree of treatment is doubtful, this method is not favoured by many authorities. Nevertheless, it is very much used for the disposal of tank effluent and, provided that there are no dangers to water supplies, sub-irrigation is less liable to cause nuisance than broad irrigation or land filtration, because septic tank effluents, exposed to the air, can be very offensive.

No exact recommendation can be given as to the area of land required for sub-irrigation : sub-irrigation is considered to be a means of soaking away effluent without much regard to treatment and a system is considered satisfactory if the subsoil is such that it permits soakage to the desired extent. However, it follows that sub-irrigation is possible only where land filtration would be possible, and consequently it is reasonable to suggest that the area of land that would be required for treatment by land filtration might also serve for sub-irrigation.

SANITATION OF BUILDINGS.

The sanitation of buildings consists of the provision of waterclosets, slop sinks, urinals, sinks, baths, lavatory basins, etc., and the drainage of the wastes discharged therefrom. The sewage from waterclosets, slop sinks and urinals is considered, 'soil-sewage,' as is any mixture of this sewage with any other drainage. The drainage from sinks, baths, lavatory basins, etc., and any surface water mingled therewith is described as 'waste' or 'sullage': and the drainage arrangements for carrying it away can be different from those used for soil sewage. Water from roofs

and paved areas is described as 'surface-water' and the drainage arrangements therefor differ from those required for waste or sullage drainage and for soil drainage.

Where there is a combined sewerage system, soil, waste or sullage, and surface-water are combined together before they are discharged to the public sewer. Where there is a separate system, soil and waste are combined together before they are discharged to the soil sewers : surface-water is kept separate and discharged to the surface-water sewers.

Where surface-water is discharged to a waste or to a soil drain, a gully or disconnecting trap is provided to prevent air from the waste or soil drain escaping to free air via the surface-water connection.

Systems of Soil- and Waste-Pipes.

In the traditional or 'two-pipe' system of sanitation, soil and waste are discharged to separate stack-pipes, and where the waste is discharged to the soil drains a gully or disconnecting trap is provided to prevent foul air from the soil drain passing through the waste drain and stack-pipe.

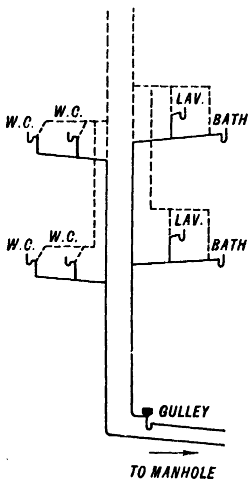

FIG. 8.—Two-pipe System of Sanitation.

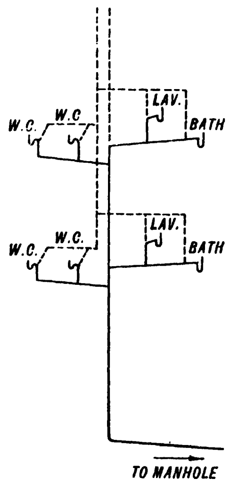

FIG. 9.—One-pipe System of Sanitation.

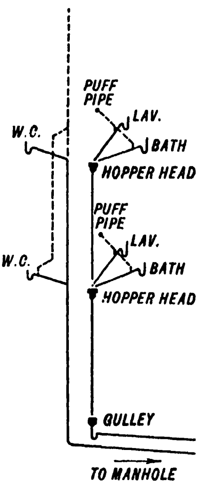

FIG. 10.—Old-fashioned Two-pipe System Involving Hopper-heads and Puff-pipes.

In the 'one-pipe' system, both soil and waste fitments are connected to the soil-stack, there being no separate stacks or drains for waste ; and, as an added protection against the escape of foul vapours into premises, the waste fitments are all provided with 'deep-seal' traps having a water-seal of not less than 3 ins. Both one-pipe and two-pipe systems, different as they are in principle, generally comply with *Ministry of Health Model Byelaws Series IV Buildings* and with London County Council By-laws (at the time of writing under revision).

There is an old form of two-pipe system largely used throughout the country, because it is inexpensive, but not now permitted in London County because it is considered inferior. In this system, the waste pipes from fitments on the ground floor discharge over a gully or a channel leading to a gully (this is permissible everywhere), and the waste pipes from fitments on upper floors discharge into open hopper-heads at the tops of stack-pipes which, in turn, discharge over gullies. (This is not permissible in London County.)

The design of sanitary systems for buildings is based on the need for interception of foul air in order that it shall not flow from the sewers or drains into buildings or elsewhere where a nuisance could be caused. This involves the provision of water-seals or traps, which in turn involve the provision of anti-siphonage pipes, and ventilation pipes (the main purpose of which is to prevent the siphonage of the traps, the second purpose of which is to ventilate the drains).

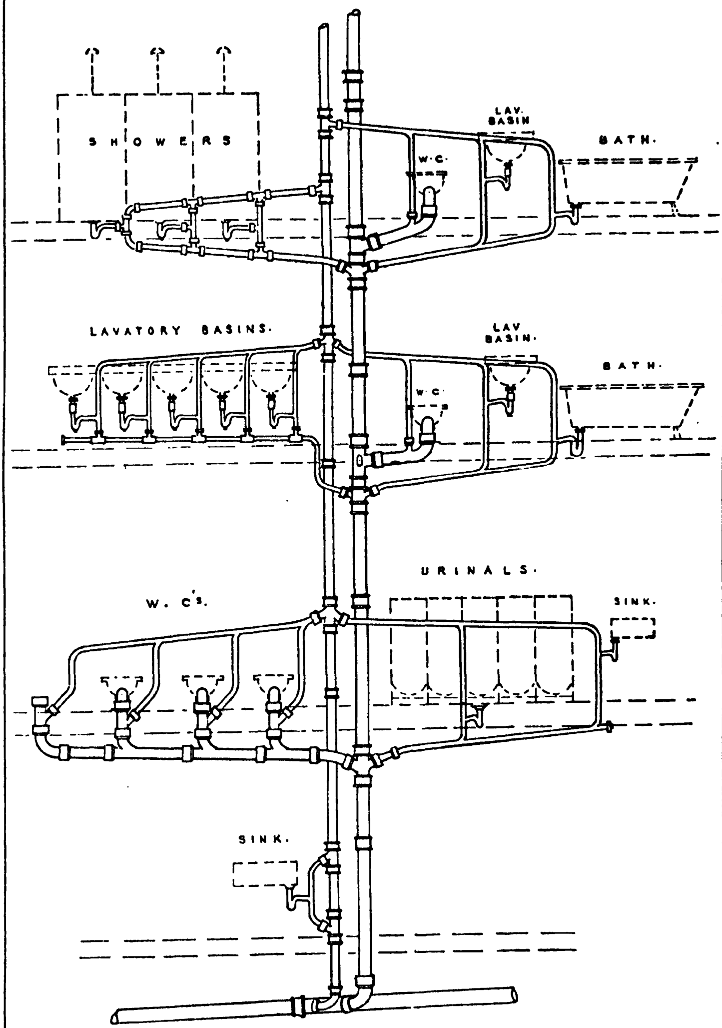

FIG. 11.—Typical example of One-pipe System of Sanitation.

The *Ministry of Health Model Byelaws Series IV Buildings*, which are the basis of local authority by-laws other than in London County, require that:

'every inlet to the drain, other than an inlet provided for the ventilation of the drain, shall be properly trapped.

'A waste pipe from a bath, sink (not being a slop sink), bidet or lavatory basin, and a pipe for carrying off dirty water, shall—

. . . .

'(2) if it discharges to a drain otherwise than by a soil pipe from a watercloset or a waste pipe from a slop sink, be disconnected from the drain by a trapped gully with a suitable grating above the level of the water in the trap;

'(3) if it is more than *six feet* in length, be provided with a suitable trap;

'(4) if it discharges into a soil pipe from a watercloset or a waste pipe from a slop sink, be provided whatever its length with a suitable trap adequately secured against destruction of the water seal.'

'The drains intended for conveying foul water from a building shall be provided with at least *one* ventilating pipe, situated as near as practicable to the building and as far as practicable from the point at which the drain empties into the sewer or other means of disposal:

'Provided that a soil pipe from a watercloset, or a waste pipe from a slop sink, constructed in accordance with these byelaws may serve for the ventilating pipe of the drain, if its situation is in accordance with this byelaw.'

'The soil pipe from a watercloset, and the waste pipe from a slop sink, other than parts of such pipes carried up as ventilating pipes, shall be—

. . . .

'(2) of an internal diameter not less than that of any pipe connecting it with the watercloset or slop sink, and in any case not less than *three inches*.'

'A ventilating pipe to a drain, and the part of a soil pipe from a watercloset or of a waste pipe from a slop sink which is carried up as a ventilating pipe, shall—

. . . .

'(2) be not less than *three inches* in internal diameter;

'(3) be carried upwards to such a height and in such a manner as effectually to prevent the escape of foul air from the drains into any building;

'(4) be covered at its open end, as a protection against obstruction, with a wire cage of copper or galvanized iron or other not less suitable cover admitting the free passage of air.'

'A ventilating pipe to a drain, a soil pipe from a watercloset, and a waste pipe from a slop sink, . . . shall not—

'(1) have a trap at its point of junction with the drain, or (except where necessary as part of the apparatus of any watercloset or slop sink) in any other part of the pipe;

'(2) have any bend or angle, except where unavoidable in which case the bend or angle shall be as obtuse as possible and shall not reduce the internal diameter of the pipe:

'where the watercloset discharges into a soil pipe which also receives the discharge from another watercloset, or from a bath, sink, urinal, bidet or lavatory basin, the trap of the watercloset shall be ventilated by a pipe which shall—

'(*a*) have an internal diameter of not less than *two inches*.

'(*b*) be connected with the arm of the soil pipe at a point not less than *three* and not more than *twelve inches* from the highest part of the trap, on that side of the water seal which is nearer to the soil pipe;

'(*c*) either have an open end as high as the top of the soil pipe or be carried into a soil pipe at a point not less than *three feet* above the highest connection to the soil pipe;'

'if the urinal can be entered from within the building, and is constructed to discharge into a soil pipe which also receives the discharge from another urinal, or from a watercloset, bath, sink, bidet or lavatory basin, the trap of the urinal shall be ventilated by a pipe which shall—

'(*a*) be of an internal diameter not less than that of the trap or *two inches*, whichever is less;

'(*b*) be connected with the waste pipe from the urinal at a point not less than *three* and not more than *twelve inches* from the highest part of the trap, on that side of the water seal which is nearer to the soil pipe; and

'(*c*) either have an open end as high as the top of the soil pipe or be carried into a soil pipe at a point not less than *three feet* above the highest connection to the soil pipe.'

Standards of Sanitary Equipment.

The minimum requirements of sanitary convenience in factories are laid down in *S.R. & O.*, 1938, *No.* 611. In brief, they are as follows :—

'There must be one watercloset for every twenty-five females and one for every twenty-five males, and in calculating the number, any odd number of persons less than twenty-five counts as twenty-five. In premises where the number of males exceeds one hundred, and sufficient urinal accommodation is also provided, there must be four waterclosets for the first hundred persons and one for every forty additional persons, and where the number of males exceeds five hundred, and the district inspector has certified that there is proper supervision and control in regard to the use of the conveniences, it is sufficient for one sanitary convenience to be provided for every sixty males in addition to sufficient urinal accommodation.'

The minimum standards for schools are given in *S.R. & O.*, 1945, *No.* 345.

For a high standard of provision in offices, etc., the figures given in Tables XII and XIII are recommended.

TABLE XII.—ACCOMMODATION FOR MEN.

No. of Staff.	W.C.'s.	Lavatory Basins.	Urinals.
1– 6	1	1	0
7– 15	1	1	1
16– 25	2	2	1
26– 35	2	2	2
36– 45	3	3	2
46– 65	3	3	3
66– 70	4	4	3
71–100	4	4	4
101–133	5	5	5
134–166	6	6	6
167–200	7	7	7

For every additional 40 persons, add 1 closet, basin and urinal.

TABLE XIII.—ACCOMMODATION FOR WOMEN.

No. of Staff.	W.C.'s.	Lavatory Basins.
1– 12	1	1
13– 15	2	1
16– 25	2	2
26– 35	3	2
36– 40	3	3
41– 57	4	3
58– 65	5	3
66– 77	5	4
78–100	6	4
101–120	7	5
121–133	8	5
134–140	8	6
141–160	9	6
161–166	10	6
167–180	10	7
181–200	11	8

For every additional 25 persons, add 1 closet; and for every additional 40 persons, add 1 lavatory basin.

Sizes of Drains.

Domestic soil flows, even from moderately extensive factories, are small generally, and in most circumstances drains of the minimum permissible diameter of 4 ins. are adequate. In very large

establishments, sizes of soil drains may be calculated in the same manner as those of soil sewers, or, in intermediate cases, they should be based on the maximum *simultaneous water demand* of the fitments served.

The peak rate of flow from an individual house can be taken as the discharge of one water-closet, approximately 3 cu. ft. per minute. The discharge from larger premises can be based on the simultaneous water demand, which is estimated as follows :—

The water demands of individual fittings are approximately :

½-in. bib-tap	0·4 cu. ft. per minute.
¾-in. bib-tap	0·9 „ „ „ „
1-in bib-tap	1·6 „ „ „ „
Watercloset W.W.P. tank	0·25 „ „ „ „
Shower roses	0·6 to 1·2 cu. ft. per minute.

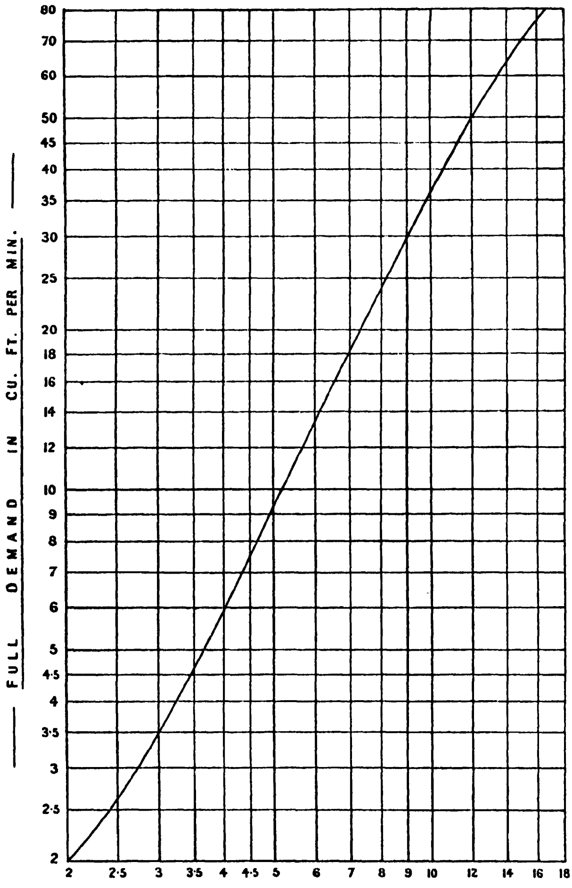

FIG. 12.—Curve of Simultaneous Water Demand of Sanitary Fittings.

The demands of all fittings except showers are totalled, but as all fittings are not likely to be used at one time, the simultaneous demand is found according to Fig. 12. To this is added the total for showers, because these are often used simultaneously. When flow exceeds those shown on the diagram, it should suffice to allow for four times average dry-weather flow.

In most instances individual premises are so small that the time of concentration of the surface water drains is negligible and therefore the Lloyd-Davies method cannot be applied. Theoretically, this would mean that a maximum rainfall of 3 ins. per hour should be allowed, but in practice it is found that, in small systems, surcharge and the storage of water in manholes makes provision for high rates of rainfall unnecessary. Consequently, flat rates have been applied, different authorities recommending very different rates. It appears that present day opinion is centering round an allowance of 1½ ins. of rainfall an hour as being applicable to all sites which are so small that the time of concentration of the drainage system is less than ten minutes.

The gradients of soil drains generally need to be somewhat steeper than those of sewers because they often receive little flow. Table XIV gives the recommended minimum gradients of 4-in. or 6-in. soil drains according to the estimated maximum rate of flow during the day, or flow based on the simultaneous water demand.

TABLE XIV.—MINIMUM GRADIENTS OF DRAINS OF 4-INS. OR 6-INS. DIAMETER.

Peak Daily Flow in Cu. Ft. per minute.	Gradient 1 in:
3	50
4	60
6	80
8	100
10	120

Well filled surface-water drains can be laid at the gradients recommended for sewers, with the addition of a minimum gradient for 4-in. drains of 1 in 90.

The above are recommendations based on both theory and practical experience. It should be stated that difficulties may be experienced with building inspectors, who still adhere to obsolete rules of thumb requiring much steeper gradients, although by-laws seldom include specific requirements as to gradients.

Materials for Sanitation of Buildings.

Waterclosets.—The pan (B.S. 1213), usually of fireclay, has an S-trap with outlet pointing vertically downwards for ground floor use, or a P-trap with inclined outlet for upstairs use. The standard pan in general use is known as the 'wash-down' type. A superior type, known as the 'siphonic' closet, has the advantage of effectively removing floating solids such as tend to remain in the wash-down closet. Earlier forms such as the wash-out closet, valve closet, etc., are obsolescent.

Watercloset suites are 'high level' or 'low level' according to the position of the flushing tank (water waste preventer). Flushing tanks generally fall under one or two heads, the 'bell-type siphon and the 'improved' siphon. The capacity of tank varies from 2 to 3½ gallons according to water undertakers' restrictions. Flushing valves as a substitute for tank-with-siphon are generally not approved in this country, but are used overseas. Special Eastern type closets for people who adopt the squatting position are manufactured for distribution to the Near East, India, etc.

Baths.—Baths (B.S. 1189) are usually cast iron porcelain enamelled, and in two patterns, 66 ins. and 72 ins. long, and are arranged to be with or without side panels. To satisfy the by-laws of many water undertakers, the overflow must discharge into free air and *not* be connected to bottom of trap on waste pipe.

Lavatory basins.—Lavatory basins (B.S. 1188) are usually of earthenware, fireclay, vitreous china, etc.: main sizes 22 ins. by 16 ins., and 25 ins. by 18 ins. They should be fixed with the top 2 ft. 7 ins. above floor level.

Sinks.—Sinks (B.S. 1206) are manufactured in fireclay to standard sizes, 30 ins. by 18 ins. by 10 ins., and 24 ins. by 18 ins. by 10 ins. without shelves: also 30 ins. by 21 ins. by 10 ins., and 24 ins. by 21 ins. by 10 ins. with back shelves.

Fireclay Washtubs and Tub-and-sink Sets.—These (B.S. 1229) consist of a combination of a washtub and a sink in one piece, a washtub and a sink in two pieces to be used together, or an individual washtub.

Metal sinks (B.S. 1244) are constructed of porcelain enamelled cast iron, porcelain enamelled pressed steel, stainless steel, or Monel metal. The units consist of a single sink with or without back ledge, combined sink and draining board with or without back ledge, and combined sink, draining board and work slab with or without back ledge.

Fittings.—Fittings used for plumbing consist of bib-taps with inlet from back, pillar-taps with inlet from below, stop valves, ball valves. The types of ball valves used include the Croydon type, the Portsmouth type (B.S. 1010) and the Equilibrium type.

Soil-and-vent-Pipes.—The majority of soil-and-vent pipes are constructed of cast-iron soil pipe and fittings (B.S. 416) jointed and caulked with lead. Lead pipe is also used for complete installations, for making-up pieces in cast iron installations, and for negotiating difficult bends. Copper pipe has been used recently in pre-fabricated work.

Waste-and-vent Pipes.—Waste-and-vent pipes outside buildings are usually of cast iron or lead; copper is rarely used. Inside buildings either lead or copper pipe is used.

Urinal wastes are preferably of lead and of no other material. Laboratory wastes should be of 'chemical lead.'

The following are suitable joints for good quality work in various materials:—

Lead to Lead.—For most purposes lead pipes are jointed together or junctions inserted by a plumber's wiped joint. When, however, lead piping is required for acids and 'chemical lead' is used, and in other circumstances where a soldered joint is undesirable, a 'lead burned' joint is used. 'Lead burning' is welding of lead work by oxy-acetylene using a pure lead filler rod.

Lead to Cast Iron.—The lead pipe is wiped to a brass caulking sleeve which is inserted in the socket of the cast iron and secured by a caulked lead joint. Where chemical lead is used the lead pipe is carried *through* a caulking sleeve of adequate size and burned to it.

Copper to Copper.—Heavy copper tubes of the kind that are used underground are frequently jointed by screwed joints in the same manner as screwed iron barrel. Light weight copper tube is too thin to take a standard screw thread and for this reason a number of other methods of jointing are employed.

Perhaps the most commonly used in the compression joint. There are many proprietary compression joints on the market, some of which necessitate deforming the tube at the point of junction, but the majority of which secure a watertight joint by squeezing a soft copper ring between the outside of the pipe and the inside of the brass coupling unit. The neatest appearance is obtained by the use of a capillary type fitting. This is a sleeve of brass which closely fits over the copper tube and is secured thereto by solder which is drawn through the annular space by capillary attraction.

Weldable fittings are somewhat similar to capillary fittings in appearance, but are secured in position by bronze welding.

Copper may be welded pipe-to-pipe, without any fittings, with bronze welding material or brazed with silver solder or other hard solder. This last method is at present not much in use for site work, although it is largely used in the assembly of pre-fabricated work such as the sparge of pipes of urinals. It is, however, by no means unsuitable for site erection of pipe-work.

Copper to Lead.—Lead pipe is jointed to copper pipe by plumber's wiped joint.

Copper to Cast Iron.—What is often considered the best arrangement for jointing copper to cast iron is the use of a caulking sleeve having a coupling for copper and a spigot which is inserted into the socket of the cast iron pipe and jointed with a caulked lead joint.

Copper to Stoneware.—A caulking sleeve having a coupling for copper may be used and be jointed to the stoneware pipe with cement mortar. Alternatively, the end of the copper pipe may be flanged out, inserted in the stoneware socket and jointed with cement mortar, in the same manner as stoneware pipes.

Drains.—The majority of drains to premises are of stoneware or fireclay pipe as used for sewers protected with concrete as required by local by-laws. Drains under buildings are preferably of cast iron (B.S. 437): it will be noted that a different specification of cast iron pipe is used for drainage than is used for sewerage.

Fittings.—Standard stoneware fittings are specified in B.S. 539, and cast iron fittings included in B.S. Schedule 1130. These include gullies, access shoes, disconnecting traps, rodding eyes and cast iron bolted accesses.

CRANES AND CRANE APPLIANCES

CRANES.

(Revised by John H. Huntley, M.I.E.S.)

British Standard Specifications for cranes are now issued as follows :—

Derrick Cranes	No. 327—1934 (under review).
Locomotive Cranes	No. 357—1930.
Electric Overhead Travelling Cranes .	No. 466—1947.

A specification for dockside cranes is in course of preparation and a specification for overhead heavy duty overhead travelling cranes used in iron and steel works will shortly be issued by B.I.S.R.A.

General Notes on Cranes.

The selection of a crane for any particular service is governed by several factors, such as load, space available, power at disposal of user, frequency and speed of operation, height of lift, duration of service and cost.

In power stations, stores, and places where an occasional lift is all that is required, a hand crane is quite suitable, even for loads up to 20 or 30 tons, but for frequent operation, or where the load has to be moved a considerable distance, it is advisable to instal a power-driven crane, even for a load of a few hundredweights, as the saving in time and labour soon pays for the difference in initial cost.

The electric crane has the following points in its favour :—

1. Simplicity of operation.
2. No power consumed whilst crane is standing.
3. Power used varies in proportion to load.
4. Always ready for starting up.

The steam crane has the advantage that it can be used wherever a supply of fuel and water is available, but time is lost in raising steam, and fuel is consumed in keeping up steam between the lifts.

Hydraulic cranes are only economical in operation when constantly working under full load, as the water consumption is the same for light or heavy loads, although by means of double-power rams attempts have been made to overcome this defect. Trouble is caused by frost in exposed situations. Hydraulic cranes are still largely used in shipyards and boiler shops, for handling plates, portable riveters, etc., where a small lift at slow speed is required. The working hydraulic pressure is usually 1,500 lbs. per sq. in., but may be as high as 2 tons per sq. in.

Pneumatic power is applied only to small hoists and pulley blocks, the air pressure being usually about 100 lbs. per sq. in.

The use of steam as the motive power on portable jib cranes has been, to a large extent, superseded by the high compression oil engine, which is either coupled direct to the crane motions by clutches or the engine is used to drive an electrical generator to supply current to motors geared to the different motions. This latter arrangement is preferable as it eliminates reversing clutches and si mplifies the duty of the operator.

The objection to the internal combustion engine for cranes is its non-reversibility necessitating the use of reversing clutches for each motion.

HAND OVERHEAD TRAVELLING CRANES.

For hand cranes up to 40 ft. span and loads up to 5 tons, a single girder crane can be adopted, but for longer spans and heavier loads it is advisable to use the double girder type to obtain lateral stiffness.

Light cranes are usually operated from the floor level by hanging chains, but for cranes above 10 tons it is advisable to work them from the crane platform. The pull on a hand chain should not exceed 40 lbs. per man, and for crank handles not more than 25 to 30 lbs. per man. The handles should have a radius of 16 ins. to 18 ins. and the centre be at a height of from 2 ft. 6 ins. to 3 ft. above platform level.

Travelling wheels for both crab and crane are usually of cast iron, and should be fitted with ball or roller bearings.

The hoisting gear should be efficient, preferably with machine-cut teeth, pinions of mild steel, wheels of cast iron, and should be fitted with a self-sustaining brake which requires to be released by the operator before the load can be lowered, but which is inoperative in the hoisting direction. This condition can be obtained by an internal ratchet or a screw disc brake.

Worm gear should have a coarse pitch and the sustaining power of the crane should not be dependent upon the inefficiency of the gear.

ELECTRIC OVERHEAD TRAVELLING CRANES.

For engineering shops, foundries, steelworks, etc., the overhead electric travelling crane is unequalled for general service.

The motions of hoisting, traversing and travelling are generally arranged, and a separate motor should be fitted for each motion. An auxiliary hoist having a lifting capacity of about one quarter the main hoist is desirable on cranes above 40 tons capacity, and should be operated by an independent motor.

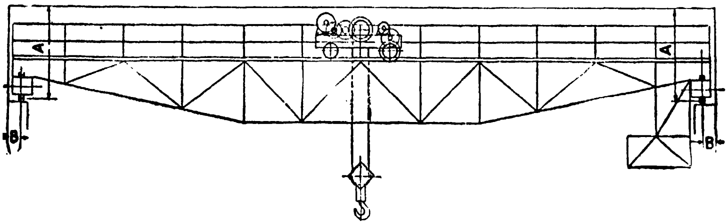

FIG. 1.

The following are particulars of standard 3-motor overhead travelling cranes (fig. 1), 30 ft. lift :—

The above table is for cranes on four travelling wheels.

For 70-ton cranes and upwards the usual practice is to mount the crane on eight travelling wheels, and the wheel loads in the following table are based on this. The column headed 'Centres of Wheel Bogies' indicates the distance between the centre of each pair of wheels in each end carriage, and the following column gives the distance between the two wheels of each pair:—

Size.	Span.	Head-room A.		End Space B.		Crs. of Wheel Bogies.		Bogie Wheel Centres.		Max. Press. per Wheel.	Wt. of Crane.	Speeds in F.P.M.			Falls of Rope.

NOTE.—The headroom figures allow for about 3 ins. clearance and the end space for about 1½ in. clearance.

The speeds of working given above are for general engineering shops: for steel works the hoisting speed should be doubled and the other motions increased by 50 per cent.

For short-span cranes of small size, a pair of 'H' beams make an economical set of girders, but the span should not exceed sixty times the width of the flange of one girder. For cranes up to 60 ft. span the most economical construction is the trapezoidal single web girder, with lattice auxiliary connected to the main girder by horizontal and diagonal bracing. This makes a very stiff construction, is easy to manufacture, and all surfaces are accessible for painting. The platform and travelling gear can be well supported by bearers between the main and auxiliary girders. For long spans and for outside service it is desirable to make the girder of the lattice

type to reduce weight and wind surface. The depth of the girder is usually made one-twelfth the span. The maximum bending moment due to the crab, assuming each wheel equally loaded, is given by the formula :—

$$\frac{W}{2S}\left(S-\frac{B}{2}\right)^2 \text{ ft.-tons,}$$

where,

W = load per wheel in tons ; S = span in feet ; B = wheel base of crab in feet.

To this must be added the bending moment due to the deadweight of the girder and travelling gear. The modulus of the girder section should be such as to give a stress not exceeding 6 tons per sq. in. in tension. The stresses in lattice girders are best determined by graphic methods.

See B.S.S. No. 466 for rules on working stresses.

The end carriages can be constructed of channels, and built up of plates and angles, when larger sections are required. They should be connected to the girders by large gusset plates, and fitted bolts to prevent cross winding. The wheel base should preferably be one-fifth to one-sixth of the span.

Rail wheels should be of cast steel, or of cast iron centres with steel tyres shrunk on the outside. The width of the rolling surface of the rail is an important point, and for heavy loads a rounded surface should be avoided. The safe load on a wheel may be arrived at by the following empirical formula :—

For cast steel wheels, safe load in pounds = 800 × W × D,
" steel tyred " " " " = 1,200 × W × D,

where,

W = width of rail face in inches ; D = dia. of wheel in inches.

These figures are suitable for cranes for machine shops, in power stations. For heavy duty cranes in constant use the factors should be reduced to 600 for cast steel wheels and 750 for tyred wheels. The steel castings should in all cases be of hard wearing quality to B.S.S. 24.

To calculate the power required to travel a crane a tractive effort of 60 to 70 lb. per ton is a safe average figure, and if the crane is working in the open, the motor should be powerful enough to move it against a wind pressure of 5 lb. per sq. ft. applied to the exposed area if the girders are of the plate type or if the girders are of the lattice type 1½ times the exposed surface of a single girder may be taken as the area subject to the pressure of the wind. The application of roller bearings to the crane axles will decrease the tractive effort by approximately 50 per cent.

To prevent cross winding the cross shaft should be stiff enough to avoid undue torsional deflection when the driving wheels are unequally loaded due to the crab being at one end of the span. A foot brake should be fitted to the cross shaft on cage control cranes and a solenoid brake fitted to the motor shaft on all cranes working in the open.

The crab frame should be built up of steel sections well stiffened to form a rigid support for the motors and gearing. Seatings should be provided for all bearing brackets consisting of steel strips riveted or fusion welded to the frame and machined in position.

The traversing wheels should be of cast steel and on the larger sizes of cranes have rolled steel tyres shrunk on to cast iron or cast steel centres.

It is not necessary to fit a brake on the traversing motion unless the speed exceeds 100 ft. per minute or the axles are fitted with ball or roller bearings.

The load is preferably lifted on wire ropes winding on to a cast iron drum rotated by gearing, the number of falls of rope depending upon the load. For cranes up to 3 tons capacity, the load may be lifted on two falls winding one fall on to the barrel. Where four or more falls of rope are used, two falls should wind on to the barrel, which should have right and left-hand spiral grooves and thus keep the load central between the girders.

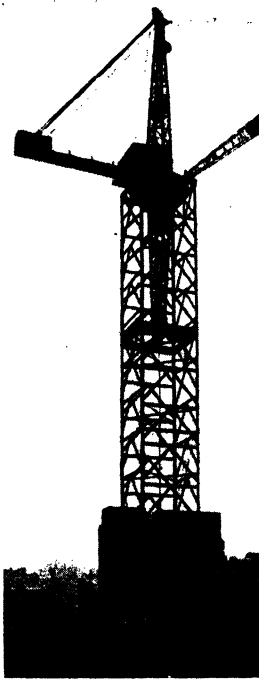
The efficiency of the gearing varies from about 75 per cent. on small cranes to 65 per cent. on large cranes. A convenient rule to determine the horse-power of the hoisting motor is

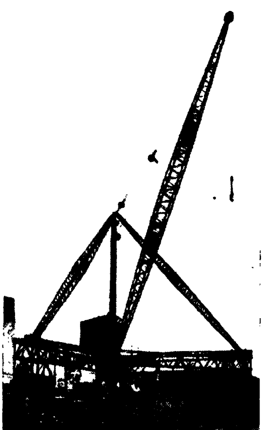
$$\text{H.P.} = \frac{\text{foot-tons per minute}}{10}$$

on a crane with gun-metal bearings. For a crane with ball or roller bearings and gears working in oil baths, foot-tons per minute divided by 12 will provide the motor of ample power.

The speeds of working given in the table, pp. 802, 803, are suitable for general engineering shop work, but for steelworks very much higher speeds are used, and as continuous night and day service is the general practice in these works the design of the crane should be specially considered and made very robust.

The hoisting motion is preferably fitted with two brakes, one of which should be an automatic solenoid brake ; the type of the other brake will depend entirely on the service for which the crane is used.





The Overhead Traveller lends itself to ready adaption for specific duties such as handling molten metal in ladles, serving soaking pits, stripping ingots from moulds, handling rods, pipes and long sections with magnets, charging furnaces, working with grabs, handling heavy forgings under the press and so on.

Ladle cranes have been made up to 250 tons capacity, but the general practice is to instal cranes from 100 to 125 tons capacity. These cranes are provided with two crabs and the larger sizes with four cross girders, the main crab then travelling on the two outer girders and the auxiliary crab on the two inner girders and underneath the main crab. The main crab is fitted with two barrels and the lifting ropes pass between the main and auxiliary crab girders.

In the smaller sizes of ladle cranes, there are usually only two girders, the main crab travelling on the top and the auxiliary crab on a track carried from the lower flange. The main hoist ropes then pass outside the girders.

The auxiliary crab has usually a lifting capacity of about 20 per cent of the main crab.

For handling forgings under the hydraulic press, the crane should be fitted with relieving gear to prevent overload due to the action of the press in pulling down a forging which is suspended not quite level with the anvil. This relieving gear may consist of a spring suspension incorporated in the snatchblock, but it is better to arrange for automatic easing off the brake as the overload is applied.

Cranes of this type have been made up to 300 tons capacity and they are usually fitted with detachable gear for rotating the ingots.

A useful attachment to an Overhead Crane is an underhung jib as this increases the area served by the crane and allows of it handling goods from one bay to another.

For outside service, the Goliath Crane gives the same service as an Overhead Traveller without the cost of erecting a gantry and the cross girders may be cantilevered out at each end so that the crane will serve an area beyond that enclosed by the track rails.

Derrick Cranes.

The Scotch derrick cranes extensively used by civil engineers and building contractors should be made to comply with B.S.S. No. 327 (at present under revision), which has been drawn up with a view to avoiding the numerous accidents which have occurred with this type of crane. Many cranes manufactured before this specification was issued had a rather low factor of safety and great care should be taken when using these cranes at anywhere near their normal load capacity.

All derrick cranes should be fitted with an indicator to give visible and audible warning to **the driver when the full load is exceeded.**

Purchasers and users of cranes should consult Statutory Instruments, 1948, No. 1145, 'The Building (Safety, Health and Welfare) Regulations, 1948.'

Locomotive Cranes.

For general service on railway sidings around works and shipyards the locomotive steam or Diesel crane is unequalled. These cranes are made in standard sizes up to 10 tons capacity and lift the load free on track with the jib in any position.

The following table gives particulars of standard steam cranes :—

Standard Locomotive Steam Cranes, 4 ft. 8½ in. Gauge.

Size.	Radius.	Size of Engines. (Cylinders.)	Size of Boiler.	Steam Press.	Speeds.			Weight.
					Hoist,	Slew,	Travel,	
Tons.	Ft.	Ins. Ins.	Ft. Ins. Ft. Ins.	Lbs.	f.p.m.	r.p.m.	f.p.m.	Tons.
3	16	7 by 10	7 9 by 3 6	100	80	2½	350	14½
5	16	8 by 10	8 3 by 4 0	100	80	2½	350	22½
7	16	8 by 12	8 3 by 4 0	100	50	2	300	32½
10	16	9 by 12	9 0 by 4 0	100	40	2	250	45
15	16	9 by 12	9 0 by 4 0	100	40	1½	200	54

For cranes of longer radius or greater lifting capacity than the above, blocking girders and rail clips are fitted to give the necessary stability, or the cranes may be made heavier.

Cranes that are to travel round sharp curves should have sliding axle gears or differentia gears and the conditions pointed out to the crane makers at the time of ordering.

The gearing **should be of steel throughout.**

The slewing spur-ring forms the roller path and should rest on a machined seating on the truck, the pressure of the slewing rollers being sufficient to hold it in position for normal working, but in the event of sudden loads it will slide sufficiently to absorb the shock and prevent damage to the gearing.

The engines are usually of the double cylinder non-condensing type, cranks at right angles and cut off at about three-quarter stroke. The boiler is of the vertical cross-tube type for a working pressure of 80 to 100 lbs. per sq. in. and should be lagged. Two means of feed should be fitted, and the incoming water should enter above the firebox and not impinge directly on the heated plates.

The mountings should preferably be flanged, and secured by studs to pads riveted to the shell of the boiler, rather than screwed directly to the shell. The safety valve should be separate and not a combined mounting with the stop valve.

A list of standard boiler mountings would consist of

1 steam-pressure gauge with syphon;
1 water gauge with plate glass protection;
1 spring loaded safety valve;
1 steam stop valve;
1 injector with steam cock and feed check valve
2 test cocks;
1 steam jet cock and pipe to funnel;
1 blow-off cock.

The feed pump may be either a steam donkey pump or be driven direct from the engine crosshead.

B.S.S. No. 356, 1930, should be followed as a guide for the construction of these cranes.

Steam Breakdown Cranes

for use on the permanent way, have been made up to 100 tons lifting capacity, but in Great Britain the usual size is from 10 to 35 tons. The truck of these cranes is provided with the usual permanent-way fittings and the axles are spring borne. The maximum load per axle with the crane in running order should not exceed 18 tons. When the crane is 'in train' the travelling gear should be disconnected and the superstructure locked to prevent it turning. Owing to the limited space due to the crane having to clear the loading gauge, a comparatively small size boiler must be fitted, and this should be of the multitubular type as the ordinary cross-tube boiler would not generate sufficient steam.

Mobile Cranes.

Mobile cranes fitted with either solid rubber or pneumatic-tyred wheels or endless chain tracks have proved of great value on the dockside, in warehouses and for general contracting work where there are no rail tracks or gantries. The crane is fitted with internal combustion engine as a source of power, which makes it independent of external sources of supply and the engine may be either coupled direct to the different motions or used to drive a generator on the crane supplying power to electrical motors for driving the different motions. The capacity for this type of crane is limited as it depends upon its dead-weight for stability. A typical crane can lift 2 tons at 18 ft. outreach and 5 tons at 10 ft., but they have been made to lift up to 15 tons.

Wharf Cranes.

For dockside service in loading and unloading ships, the high gantry type of jib crane is principally used. The usual sizes are from 1½ tons to 5 tons and the radius from 40 to 60 ft. The gantry is made wide and high enough to admit of the passage of rolling stock underneath and to keep the jib clear of the sides of large vessels. A separate motor should be fitted for each motion.

Typical speeds of working, in feet per minute, are as follows:—

Description.	Size. 1½ tons.	3 tons.	5 tons.
Hoisting	300	200	120
Slewing	500	500	400
Travelling	100	100	80
Luffing	150	150	100

For high luffing speeds some form of compensating gear is essential to reduce the power consumption due to raising the load and jib each time the radius is reduced. With the ideal compensating gear the path of the load is kept horizontal as the jib is raised or lowered, and with the jib balanced the power required is only that necessary to overcome friction.

Numerous types of compensating gear have been invented during the past few years, some of which are very complicated, and the crane user should select those of the simplest construction with the minimum number of moving parts, and pay special attention to the lead of the hoisting rope, which often suffers considerably through being passed round numerous pulleys in order to give the desired level path to the hook as the jib is raised or lowered.

The luffing motion is frequently operated by a crank, as this eliminates the use of ropes, and the throw of the crank is proportioned so that the jib cannot exceed the prescribed maximum and minimum radii.

For rapid handling of coal, ore, or similar loose materials, the transporter grab crane is unequalled. The load is carried by a trolley which travels on a horizontal track, supported in a suitable manner by the crane structure, which latter may take the form of a tower with cantilevers on each side or a bridge, if it is desired, to convey the load over a considerable distance.

If working at the dockside the outer cantilever may be made to hinge up to clear the masts and funnels of ships when coming alongside.

The operating machinery can be fixed on the structure and the trolley carry only guide sheaves for the hoisting ropes and be hauled along by other ropes winding on to a separate winch, or the hoisting and transporting gear can be carried by the trolley. The latter system is usually adopted when the gross load exceeds 5 tons, as with the fixed machinery system the wear of the ropes becomes excessive in the larger sizes and off-sets the initial saving due to the lighter design of structure.

The advantage of this type of crane over the jib crane is that the load is conveyed in a direct line from point to point instead of through the arc of a circle. The transporting speed can be at the rate of 800 to 1,000 ft. per minute, whilst the maximum safe slewing speed is not more than 400 to 500 ft. per minute. With a 3-ton grab the transporter crane will usually handle 150 tons per hour against 100 to 120 tons on a jib crane.

On the larger types the driver travels with the trolley and is always immediately above the area of operations. In some cases the trolley is fitted with a revolving jib of about 10 ft. radius, from the point of which the grab is suspended. This enables the driver to cover the whole area of the ship's hatchway without moving the main structure, resulting in a speeding up of operations.

For handling coal, ore, and similar materials, much time and labour is saved by using grabs; these may be on the single or double-chain principle.

The single-chain grab may be fitted to any crane lifting on a single fall of rope, but grabs of the double-chain type require an extra drum to coil up the opening or closing rope. This should preferably be driven through a friction drive, although for short lifts a spring drum is quite suitable.

The best practice is to use a grab of the four-rope construction, *i.e.* having two hoisting ropes and two closing ropes, with sheaves of large diameter and properly spaced, the tendency to spin is eliminated, and the grab can be opened or closed in any position. This necessitates two power driven rope drums on the hoisting winch, and within the limit of about 10 tons, a single motor drive can be used with a balancing gear between the drums to ensure that the speeds synchronise and the distribution of the load on each drum is equal. Above this load, the best practice is to have a separate motor and gear for each drum and instal an electrical system for synchronisation and equalising of the load.

Grabbing work is very severe on cranes, and the nominal size of the crane should be 50 per cent. in excess of the combined weight of grab and contents, or in other words, the factor of safety should be 10 instead of 6 to 7. The empty grab may be balanced by sliding counter weights to reduce the power consumption on jib cranes.

Automatic self-dumping single-rope grabs, which open when the weight of the grab is relieved from the hoisting rope, require only a single-drum winch for operation and give a higher duty than the single-rope grab with fixed discharge gear.

On heavy grabs it is desirable to duplicate the rope, *i.e.*, have two hoisting ropes and two holding ropes. The rope sheaves should be at least 24 times the rope diameter and well spread to prevent twisting of the ropes round each other.

CAPACITY AND WEIGHTS OF GRABS.

180	112	70	—	—	—

Shipbuilding Cranes.

For service over shipbuilding berths, high gantries with overhead travellers and mono-rail cranes, gantries with cantilever cranes, steel derricks and tower cranes, are used, and experience favours the latter type.

Tower cranes may be either of the fixed or travelling type, practice in Great Britain being inclined to the fixed type, as they require less clearance between the berths, and use is made of valuable space which would otherwise have to be kept clear for the track of a travelling crane.

The crane structure consists of a horizontal cantilever supporting the track for the load trolley, and is carried on the top of a braced steel mast which is free to revolve inside a fixed or travelling tower. The cantilever is balanced by a tail carrying the machinery, which gives the crane a hammer-headed appearance.

Due to the development of pre-fabrication in shipbuilding, the capacity of these cranes has increased in recent years and the latest installation includes cranes to lift 40 tons at 70 ft. radius and 20 tons at 140 ft. radius.

These cranes, if desired to lift varying loads at different radii, should be fitted with an automatic anti-overload device which will prevent a load above the safe limit for its radius being lifted, and will also prevent the trolley traversing beyond the safe radius for that particular load.

For fitting out, cranes of the wharf type with derricking jibs are used, and range in size from 10 to 60 tons, with radii up to 80 ft., according to requirements. Two speeds of hoisting are generally arranged, so that light loads may be lifted at a speed of 50 to 80 ft. per minute. A typical crane of this type lifts 30 tons at 55 ft., 20 tons at 72 ft., 10 tons at 80 ft. radius, and is mounted on a gantry to clear rolling stock, the centres of the gantry track being 22 ft.

Cranes of this type are installed for dry dock service, and it is occasionally necessary that they should work from both sides of the dock. This may be arranged by connecting the two sides of the dock by a track at the end and introducing turntables, or better by making the track sweep round on a curve and carrying the rail wheels on special swivelling bogies and inserting an epicyclic gear between the sections of the travelling motion cross shaft which connects the driving rail wheels on each side of the crane.

Floating cranes are occasionally used for fitting out and repair service, and have the advantage of being transferable from dock to dock, but with them it is not easy to deposit a heavy load with precision, as the crane follows the movement of the water and its equilibrium is disturbed with every fluctuation of loading.

These cranes are usually steam operated but several large cranes have been electrically driven and this practice will be extended on account of the increasing use of the diesel engine which can be used to drive an electric generator to supply current to the crane motors as well as to drive the propelling machinery.

The pontoons are usually rectangular, flat-bottomed vessels, but if self-propelled it is advisable to give them a ship shape. The angle of heel under full load conditions and a 5 lb. wind should be not more than 5°. Travelling ballast is sometimes fitted to limit the heel under various loading conditions.

Capstans.

For hauling trucks in goods stations or on the dock side a capstan designed to exert a pull of 1 ton at a speed of 150 to 200 ft. per minute is sufficient. The free bollard type with the rope attached to the bollard is more economical in use than the fixed bollard type which depends upon the friction of the coils of rope round the bollard for hauling power.

The warping of ships into position in the docks is done by capstans of from 10 to 20 tons pull A constant torque at varying speeds is the desideratum for this duty, and the characteristics of the Austin constant-current motor make it eminently suitable for this work.

Overhead Runways.

Overhead runway systems, consisting of a track formed from a single rolled-steel joist which may be curved to suit local conditions, and have switches or turntables, are frequently installed in warehouses, steelworks, gas works, and other situations where an overhead crane is unsuitable or too expensive. Hand-pulley blocks and trolleys are used on the runways for occasional service and light loads, but for speed and loads above two tons an electric trolley hoist should be installed. These may be either floor or cage controlled, and have usually separate motors for hoisting and travelling. The lifting speed may be as much as 100 ft. per minute, and the travelling speed from 200 to 800 ft. per minute, according to the duty required.

Grabs can be fitted to lift coal, ore, or similar material.

Reference should also be made to B.S.S. Handbook No. 4, 'Lifting Tackle,' and to the Electricity Factories Act, 1911. B.S.S. 449 has recently been issued dealing with the maximum stresses on structures, but the figures given therein should only be applied to cranes with a factor depending upon the duty for which the crane is intended.

STRUCTURES.

Crane structures should be made of open-hearth mild steel, 28 to 32 tons tensile strength, extension not less than 20 per cent. in eight inches. In determining the section of members, allowance should be made for the vibration due to the movement of the load and machinery, for the movement of the structure in the case of a travelling crane, and deflection should be considered where bearings for shafts are carried on structural members. The stresses should be such as to give a factor of 5 to 6 on the ultimate strength of the material. The ratio of length to radius of gyration should carefully be considered in struts, and charts plotted from Perry Robertson form a reliable basis on which to determine the stresses. For wind bracings the factor of safety need not be more than three, as this is an exceptional loading infrequently applied.

High tensile steel 37/44 tons has been used where weight is a consideration and is economical on long jibs and cantilevers where the dead weight imposes a considerable proportion of the load on the supporting structure. To obtain full advantage from the use of high tensile steel, the factor of safety should be based on the yield point which is higher in proportion to the breaking stress than ordinary mild steel.

Wind pressure on cranes in exposed positions in Great Britain may be taken as a maximum of 40 lbs. per sq. ft. It is inadvisable to work a crane in a wind pressure above 5 lbs. per sq. ft., and when designing the structure it is therefore unnecessary to allow for a higher pressure under full load conditions. The maximum wind pressure must of course be considered separately.

The revolving superstructure of jib or cantilever cranes may be carried on a ring of live rollers, or on a set of four or eight large diameter rollers designed as travelling wheels, but with conical treads and unflanged. The live rollers may be of either forged or cast steel and should run between two steel guard rings connected to the centre pin casting by radial rods. A gunmetal washer should be fitted between each roller and the outer guard ring, to take the outward thrust of the rollers. For unhardened rollers the pressure in lbs. should not exceed 400 by length in inches by diameter in inches. The roller-paths should be of steel, machined conical on the face to form a full bearing for the rollers.

On jib cranes up to about 5 tons capacity the roller-path frequently consists of a flat-bottom rail bent to a circle, and the superstructure is then mounted on four rollers 15 ins. to 18 ins. diameter. This is a cheap and serviceable construction.

A friction clutch should be incorporated in the slewing gear adjusted to slip and prevent damage in the event of excessive shock due to too sudden application of the brake or the fouling of jib with some stationary object.

GEARING.

On all high-class crane work the gearing should be machine cut. For hand and low-power cranes cast-iron wheels and steel pinions are satisfactory, but for all high-speed cranes the gearing should be of steel, with the possible exception of motor pinions, which, to ensure silent running, may be of rawhide, fabroil, or phosphor bronze.

For heavy loads and high speeds, machine-cut double helical gearing is very satisfactory, efficient and silent.

Modern practice is to enclose all gearing in cast iron, cast steel or welded steel oil baths.

The strength of spur gearing can be determined by the Lewis formula (page 976, Vol. I). For crane work Class 'C,' gears are used.

Gearing with stub teeth and 20° involute is advised for crane work, as the strength is greater than standard 14½° involute, by 30 per cent. with a rack, to 50 per cent. with a 12T pinion. The addendum is 0·27 of the circular pitch and the dedendum 0·32. With diametral pitch the outside diameter of the wheel is determined by adding 1·75 to the number of teeth and dividing by the pitch.

Worm wheels should consist of a phosphor bronze rim fixed on a cast-iron or steel centre, and have machine-cut teeth. The worm should be of high tensile forged steel and need not be hardened unless facilities exist for grinding the threads. In determining the size of worm gearing the heating effect must be considered as well as the strength.

SHAFTS.

In designing shafts the resultant loads should be determined and the effect of combined bending and twisting moments considered. The equivalent twisting moment due to combined bending and twisting is equal to

$$BM + \sqrt{(BM)^2 + (TM)^2},$$

where,

$$BM = \text{bending moment}; \quad TM = \text{twisting moment.}$$

Stresses should be low on account of the frequent reversal and impulsive loads common with crane work. Where keys are fitted, the shafts should be increased in diameter.

Where shafts are subjected to severe reversing stresses tangential keys should be fitted as they are less likely to work loose than the ordinary key and can be more easily adjusted.

BEARINGS.

For cheap hand cranes the bearings are usually of cast-iron and not bushed. All power-driven cranes should have gunmetal bushed bearings. The bearing brackets should be fitted with caps, and the bushes be in halves. Studs for securing the caps are not desirable. Tee-headed bolts should be used, and these should fit in a slot accessible from the outside of the pedestal, so that the bolts can be withdrawn after the cap is removed and without disturbing the steps. The pressure per sq. in. for shafts running at medium speeds should not exceed 600 lbs. For slow-moving pulleys and axles the pressure may be as high as 1,200 lbs. per sq. in. Fast-running shafts, such as motor spindles, should have ring lubrication. Axles are frequently fitted with float lubrication, which consists of a cylinder of cork floating in an oil-well formed in the inverted cap of the bearing and by contact with the axle supplying the necessary lubricant. But these are being gradually superseded by spring-loaded felt pads. Screw-down and spring-feed lubricators with grease are very satisfactory if they are given attention. The best practice is to install a closed high pressure grease lubrication system to all bearings, fed from a central reservoir, which automatically feeds a charge of lubricant to each bearing whenever a pressure pump is operated.

It is desirable to fit ball or roller bearings to cranes in constant operation as the smaller power consumption due to the reduced frictional losses in the bearings will soon pay for the additional cost.

ROPES (*see* SECTION XXI, PART III, *p.* 933, VOL. I).

CHAINS.

Chains should only be used for grabs or situations where the fine strands of a rope would be damaged by abrasion. The working load for a welded iron chain is given by the rule.

$$W = \frac{(\text{dia. of iron in } \tfrac{1}{8} \text{ in.})^2}{9}.$$

Weldless steel chains are about 13 per cent. stronger, and make good slings on account of **their lower weight. Steel plate driving chains are sometimes used for drives instead** of gearing, **and give good results if properly designed. The burden chain for large ingot rotating** gears is **best constructed of one inner and two outer links connected by steel studs.**

(See also page 169, Vol. I.)

BRAKES.

One of the most important features on a crane is the brake, and this should have a large factor of safety. The brakes in common use are electric, automatic solenoid, centrifugal, automatic mechanical, and manual brakes. Hydraulic and pneumatic brakes are used for heavy loads, or where extremely fine control is desired.

A typical arrangement of a solenoid brake is shown in fig. 2. The brake is applied by the weight and released by a solenoid magnet connected in the motor circuit so that it is excited immediately current is switched on to the motor.

If F is the turning force on the rim and μ the coefficient of friction between the brake shoes and sheave, then the weight required to apply the brake equals

$$\frac{C \times M \times F}{H \times L \times 2\mu}$$

where C, M, H, and L refer to the dimensions shown in fig. 2.

The weight of the solenoid plunger and levers must be taken into account, and about 10 per cent. is usually added for friction in joints.

The centrifugal brake is designed to control speed, and does not serve to sustain the load at rest. In one form it consists of a series of weighted slippers which are pressed by centrifugal action on the inner rim of a fixed annulus, and thus have a retarding effect. The brake shoes should be slightly lubricated and ample radiating surface allowed to dissipate the heat generated.

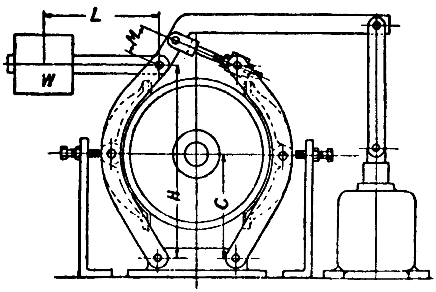

FIG. 2.

The automatic mechanical or Weston disc brake so long used on heavy cranes as a secondary brake for lowering, has been superseded by electrical systems of lowering control. Where two holding brakes are required on the hoist motion, one is arranged to come into action immediately the current is cut-off and the other to have a slightly delayed action, in order to avoid the shock which would result from double braking when stopping the load.

The pitch of the helical **faces is determined by the following formula:**

$$T = \frac{PL}{R \times \mu \times N}, \quad \text{and} \quad \frac{PL}{Tr} - f = \tan A\ ;$$

therefore,

$$\text{lead of helix} = \tan A \times 2\pi r$$

where,

R = average radius of disc ;	**μ = coefficient of friction = ·07 ;**
PL = torque on driving wheel ;	**r = mean radius of helical faces ;**
A = angle of helix ;	**T = thrust or pressure on disc ;**
N = number of rubbing surfaces ;	**f = coefficient of friction of helical faces.**

The brake should be proportioned so that an angle of helix of about 10° will give the requisite pressure. The brake should run at a speed not exceeding 150 revs. per minute, and the pressure on the discs should not be more than 200 lbs. per sq. in. and on the helical faces 500 lbs. per sq. in.

Manual brakes are usually of the band or post type. Band brakes should have a bar fitted round the outside of the strap with adjusting screws to ensure that when the brake is released the strap will come away evenly from the sheave. The connecting rods on manual brakes are being replaced by hydraulic transmission by which pressure on the foot pedal is transmitted by a column of liquid in a tube to the actual brake lever. This allows for the foot pedal being placed in any position convenient to the operator and at any distance from the brake.

Band brakes are generally only suitable for a torque in one direction, i.e. away from the fixed end of the strap.

To find the pull to be applied to the loose end of the strap, the following formula may be used:

$$P = \frac{F}{e^{\mu\theta} - 1},$$

where,

P = pull; μ = coefficient of friction;
F = turning force on rim of brake sheave; θ = angle of sheave embraced by strap in radians.
e = base of Napierian logs.

Brake sheaves are made of cast iron and cast steel, the latter material whilst being less likely to fracture than cast iron wears more quickly and where metallic bonded friction surfaces are used scores badly.

Special alloy cast irons which have a higher tensile strength than ordinary cast iron and harder surface are recommended for cranes and transporters working continually at high speeds.

The brake shoes or strap may be lined with wood, leather, or one of the asbestos fabrics such as 'Chekko' or Ferodo lining; wood and leather are inclined to char and glaze and the coefficient of friction is reduced. Bonded asbestos is not subject to these objections and maintains a constant coefficient of friction, which in practice may be taken as 0·3.

Electric cranes may be controlled by dynamic or rheostatic braking if direct current is used. Dynamic braking with potentiometer control is to be preferred to plain rheostatic braking, as practically automatic speed control is obtained in the lowering direction irrespective of the weight of the load. Heavy rushes of current and mechanical shock can be produced on the motor by either system of electric braking, and some form of current limit control should be provided.

Speeds up to twice full load hoisting speed can now be obtained without difficulty in lowering the light hook under potentiometer control.

A series solenoid should be used with this system of braking, as the current may fall too low to excite a series coil sufficiently to hold off the brake.

With alternating current where the duty is severe reverse current braking can be used to slow down the load before applying the solenoid brake. This reduces the wear on the brake.

To control the lowering of heavy loads at slow speeds, a hydraulic brake is the most efficient. In principle this consists of either a reciprocating or rotary pump with closed circuit and throttle valve.

The pump is in the train of gearing between the motor and the rope drum, and by means of a free wheel drive is inoperative in the hoisting direction. On lowering, the solenoid or other brake is released, and the descending load drives the gearing and pump. The speed is controlled by the throttle valve, and very fine regulation at constant speed can be obtained. The system is especially suitable for placing guns, turbines, and engines on board ship.

For gun tempering, armour treatment, and processes where immersion in a cooling bath is necessary, it is essential that the load should be rapidly lowered at speeds varying from 60 ft. to 150 ft. per min.

The lifting speed is about one-tenth of these speeds, and the usual practice is to disconnect the rope drum from the gearing and motor when lowering.

A coil clutch is used for the purpose, and a powerful brake must be fitted to control the lowering speed and sustain the load. Manual brakes have proved satisfactory for this purpose, particularly in conjunction with a centrifugal brake for speed control. On cranes of over 100 tons capacity elaborate electro-hydraulic systems have been used with success, but they are very costly.

Electrical Equipment.

Cranes may be worked by either direct or alternating current, but the former is to be preferred for the following reasons:

1. Series-wound motors may be used with high starting torque and speed variation in proportion to load.

2. Very fine control can be obtained and dynamic braking used.

3. Less wiring than with slip-ring motors.

Alternating-current motors usually require less attention than direct-current motors, but the starting torque is limited and the running speed is practically the same under light and full load conditions. The starting torque for alternating-current motors should be not less than two-and-a-half times the full load torque, and in fixing the horse-power it is advisable to make it about 10 per cent. higher than for direct-current motors for the same duty.

With reference to paragraph 1, it should be noted that whilst with ordinary series motors the speed increases with a reduction in the load. the variation is not very great between full and approximately half load, and as in many cases light loads are more frequently lifted, mechanical change gear is used to increase the speed and take advantage of the full power of the motor. This can, however, be eliminated by means of a special two-speed motor, designed to develop its full horse-power at two definite speeds besides having the usual series characteristic. The alteration in speed is obtained by diverting part of the field current, and with the Scott Bentley discriminator control this can be done automatically, thus relieving the operator from the trouble of changing gear and ensuring the correct speed for the weight of the load. The efficiency of the crane is increased without any added complications.

Squirrel-cage motors are not in general suitable for crane work, although a number of cranes have been equipped with special squirrel-cage motors having high-resistance rotors and giving twice full load torque at starting. The starting current is about four to five times the full load current, and the switchgear should be of robust design. These motors are not suitable for a heavy duty or for where more than about 20 h.p. is required.

The alternating current commutator motor is now a practical proposition for crane service and will give a speed range of 10 to 1 and controls the speed when lowering as well as when hoisting.

All motors should preferably be of the totally enclosed type. For ordinary engineering shop service crane motors rated to develop their full power for a period of half-an-hour with a temperature rise of 90° F. are quite suitable. For steel works and other situations where the duty is severe, the rating should be for one hour. It is desirable to have the yoke and bearings made in halves so that easy access may be had to the interior of the motor.

A special design of direct-current motor known as the Mill type is largely used on steelworks cranes. It has a steel carcase made to hinge open along the centre line to permit of easy removal of the armature. The armature is of small diameter to reduce inertia stresses on reversal, and the insulation and winding are such as to permit of stalling the motor without injury. It was originally developed for service in rolling mills, hence the name. These motors have 'Class B' insulation and are rated for a temperature rise of 75° C.

See B.S.S. No. 168, 1936.

CONTROLLERS.

For ordinary crane service and motors up to about 60 h.p. at not less than 440 volts the drum controller gives very good service. There should be ample room inside the controller for connections, all parts accessible, finger tips and drum contacts easily renewable, insulation of mica or micanite, and a definite step should be felt as the barrel is moved round to each contact. Magnetic blow-out should be fitted on direct-current controllers.

For frequent operation and large currents a solenoid operated or contactor controller should be fitted. The contactor switches handle the main current to the motor and are controlled by a small drum, or master controller, which deals only with the shunt current required to excite the contactor coils. A development of this system is the Holme Portable Remote Control, in which the master controller can be carried about by the operator and connection is made to the contactor panel by a multicore flexible cable.

Creeping control for foundry or riveting work is obtained by inserting resistance in parallel with the motor armature circuit, thus magnifying the strength of the field and enabling full-load torque to be obtained at a very slow speed.

Cam operated controllers have outwardly the appearance of drum controllers but the fingers consist of a series of simple contractors actuated by a number of cams mounted on a vertical spindle rotated by the controller handle. They are used where the current is considered rather heavy for an ordinary drum controller and yet not sufficiently heavy to justify an automatic controller.

On alternating current circuits speed regulation is obtained by resistance in the rotor circuit, but the same range of speeds cannot be obtained as with direct current, particularly on light loads.

When creeping speeds are required with alternating current the most practical method is to load up the motor with a manual brake, and then use the controller and resistance to adjust the speed.

A recent development is to use two motors connected through a differential gear. When both motors lift in the same direction the crane works at full speed but on reversing one motor the speed is reduced to about one-tenth of normal. The operation is entirely from the controller and the speed may be kept constant for an indefinite time.

Up to about five h.p. resistances are usually made of wire-wound porcelain bobbins, and above this power consist either of stamped steel grids or a drawn continuous strip bent into grid form. The grids should be well stiffened to eliminate vibration and sherardised to prevent rusting. In corrosive atmospheres, special cast-iron grids give better service than stamped or coiled steel grids.

Resistances are usually rated to be in circuit two or five minutes out of every fifteen minutes, with a temperature rise not exceeding 350° to 400° F. For creeping control ten minutes or even continuous rating is desirable. See B.S.S. No. 587–1940.

SWITCHBOARDS.

Many cranes are fitted with a main switch and fuses for the protection of each motor circuit, but it is desirable that these should be replaced by a main automatic circuit breaker and relay switches for each branch circuit. The relay switches do away entirely with fuses and obviate the loss of valuable time at critical moments due to replacing them. Each switchboard should have a pilot lamp and socket for portable lamp connection. It is advisable, although not essential, to fit an ammeter and a voltmeter.

LIMIT SWITCHES.

Limit switches to prevent overwinding should be fitted on all cranes, and if the speed of working is moderate, a shunt limit switch is suitable, connected in the no-volt coil circuit of the main breaker on the switchboard, so that in the event of the switch coming into operation the main circuit is opened at the breaker.

Special contacts can be fitted on the controller to short-circuit the limit switch on bringing the controller on to the first notch in the reverse direction. The breaker can then be reset and the motor reversed. The limit switch should be of the totally enclosed self-resetting type. On high speed cranes, a main current limit switch is desirable, as it can be designed to create a dynamic braking circuit whenever it is operated, and thus assist the solenoid brake in promptly stopping the motion.

SOLENOIDS.

Solenoids for brake operation are preferably of the series type on direct-current circuits, but if of the shunt type, a discharge resistance should be fitted to take up the induced current on breaking circuit. For alternating circuits solenoids are preferably connected in all phases. The rating of a solenoid should be the same as the motor with which it is in circuit. The coils should be enclosed as a protection against damage, dirt, and damp.

Large solenoids are being superseded by Thrustors which consist in principle of a small motor operating a pump producing a hydraulic pressure on a plunger connected to the brake lever. The apparatus is self contained in a casing similar to a direct current solenoid and is made in a range of sizes up to a maximum push of 800 pounds through eight inches. Thrustors operate either on direct or alternating current, and are preferable to solenoids on alternating current circuits.

The Lewis brake solenoid made by Ransomes & Rapier, Ltd., has two plungers, one sliding inside the other. The inner one is connected to the brake lever and is free to move independently of the outer plunger or armature. When the magnet is excited the two plungers are automatically and mechanically coupled and act as one in releasing the brake, but when the current is switched off they are disconnected and the inner plunger is free to follow the movement of the brake lever independently of the stroke of the magnet. As the brake surfaces wear the inner plunger is partially withdrawn from the outer, but owing to the automatic clutching arrangement, the full stroke of the magnet is always effective and releases the brake freely, obviating the rubbing and wear which take place with the ordinary brake if the shoes are not occasionally adjusted.

WIRING.

For crane work the current density may be in excess of ordinary practice for shop motors owing to the intermittent service, and the I.E.E. has drawn up a set of rules for this duty. See also B.S.S. No. 327, appendix iv.

Cables, unless lead-covered and armoured, should be enclosed in metal conduits. Current is supplied to travelling cranes from bare conductors stretched along the track by means of slipper or trolley collectors. The bare conductors may be of copper wire, or, as is now common practice in steel works, steel tee or angle bars ground on the sliding face.

For jib cranes the conductors may be carried overhead or in a conduit. An alternative system is to run the cables in a closed conduit with junction boxes at intervals from which connection can be made by plug and flexible cable. A drum should be fitted on the crane to coil up the slack cable.

The drum may be hand operated if the crane is infrequently moved or if the length of travel is small, not exceeding 50 ft., and the cable light a spring can be used to automatically revolve the drum as the cable becomes slack and prevent loose coils lying on the ground. Where space will permit, it is better to have a weight-operated overhauling gear to exert a torque on the drum, and lengths of heavy cable up to 150 ft. long can be handled in this manner. Cable drums geared to the travelling motion are inadvisable owing to wheel slip on the rails, which may cause a considerable tension on the cable, with resulting damage.

Electro-Lifting Magnets.

Electro-lifting magnets are largely used in connection with cranes for handling all classes of iron and steel materials, and their application shows a considerable saving in time and cost compared with manual labour or even ordinary crane service with slings.

For lifting pig iron, small and heavy scrap, and large solid masses, a single circular magnet is adopted, and for lifting long and wide plates two or more of these magnets are used spaced along a beam which can be slung from the crane hook.

As regards the *lifting of hot material*, circular magnets are unsuitable, because they offer such large heating surfaces, and the windings are so close to the heat that there is bound to be overheating. The Phœnix bi-polar magnet offers the minimum surface to the heat, and when constructed for lifting hot material the pole pieces are extended about 8 ins. at the bottom to lift the coils farther away from the heat; the pole faces are then at a distance of 12 ins. from the coils.

Steel may be handled by magnets up to a temperature of about 700° C.

The following table gives the approximate weights and lifting capacities with ingot and pig-iron for various sizes of circular lifting magnets :—

Diameter of Lifting Magnet.	Weight of Magnet.	Safe Load of Solid Steel Ingot.	Approximate Load of Pig Iron per Lift.	Current Consumption.

SECTION XXXVIII

PART II

LIFTS AND ESCALATORS

(Contributed by Col. E. B. Rook, T.D.)

ELECTRIC LIFTS.

These notes are confined to electric lifts, which for reasons of safety, cheaper operating costs, and availability of power supply have superseded the hydraulic types for all but a few special applications. The electric lift is a complex machine involving a number of individual parts, which in the main conform with normal engineering practice in their design and production. It is not the intention in these notes, therefore, to discuss such components, but rather to treat the lift as an entity and to consider those matters which affect its application and use as such.

Much useful work has been done by various bodies in recent years aimed at laying down standards and codes of practice for the design of lift installations, loads and speeds to suit various applications. These are welcome both as a means of raising the general standard of lift practice and for their tendency to do so without raising costs seriously by virtue of savings in production costs which should result from the standardisation of loads, speeds and ancillary lift equipment they advocate. Information on such standards and codes have been published from time to time, notably by the Building Industry National Council, The British Standards Institution and in Post-war Building Studies, No. 9, by H.M. Ministry of Works. These notes comply with the recommendations made in such publications and where extracts from them have been used are now gratefully acknowledged.

Recommended Layouts and Sizes for Lift-Wells and Machine Rooms.—The information given in the diagrams and tables contained in figs. 1–5 cover the use of electric lifts for those applications which lend themselves to a measure of standardisation and are, therefore, recommended for use wherever possible. Applications outside those thus covered, *e.g.* heavy or special purpose goods lifts and high-speed (above 300-ft. per minute) passenger lifts, need considering on their merits in conjunction with the lift maker. Nevertheless, they will be found to have many features in common with the details and sizes given in these figures and the amplification of them which is given below.

The Machine Room.—This accommodates the driving machine, of either the geared or gearless traction type, and its control panel and accessories. It may be placed above or below the lift-well, the former being the better position resulting in a reduced load on the building, lower capital cost, a smaller lift-well for a given size of car, reduced power consumption and cost of rope renewals. Machine rooms for high speed lifts with gearless traction should always be above the lift-well. Wherever it is placed it must be dry and weatherproof, well lighted both naturally and artificially, properly ventilated and of fire-proof construction.

The Lift-Well.—It is essential that lift doors and machinery operate as quietly as possible, but all noise cannot be eliminated. The lift-well should, therefore, be fully enclosed, even when occupying the space available in a staircase well, and so positioned as to result in the minimum of transference of audio frequencies through the main structure. Even if this be done it will remain advisable to noise insulate the lift machine by mounting it on sound insulators or a concrete block insulated from the machine-room floor by suitable anti-vibration material.

The lift-well must be finished flush internally and its use restricted to that of the lift installation, no other services being allowed in it despite the attractive position it often offers for them. Use of a totally enclosed lift-well has the added advantage of providing easy facilities for car and counterweight guide rail fixings at frequent intervals, which will add materially to the rigidity of the installation and so improve running conditions and may reduce the size of rail required.

To guard against the possibility of a totally enclosed lift-well being the means of spreading fire by acting as a flue or chimney, all landing entrances need to be fitted with fire-resisting doors or metal shield gates, and the well enclosed with solid fire-proof walls. Nevertheless, such lift-wells need to be well ventilated.

FIG. 2.—Lifts for Small Office Buildings with Solid Sliding Doors. Speeds up to 200 F.P.M.

Positioning of Lift-Wells.—Decision as to the best position for the lift-well will be dictated to some extent by the interior planning and organisation of the building concerned. This will be especially so in the case of goods lifts, but some general rules are applicable in the case of passenger lifts for office buildings and departmental stores. In the former, the lift or lifts are best sited in a

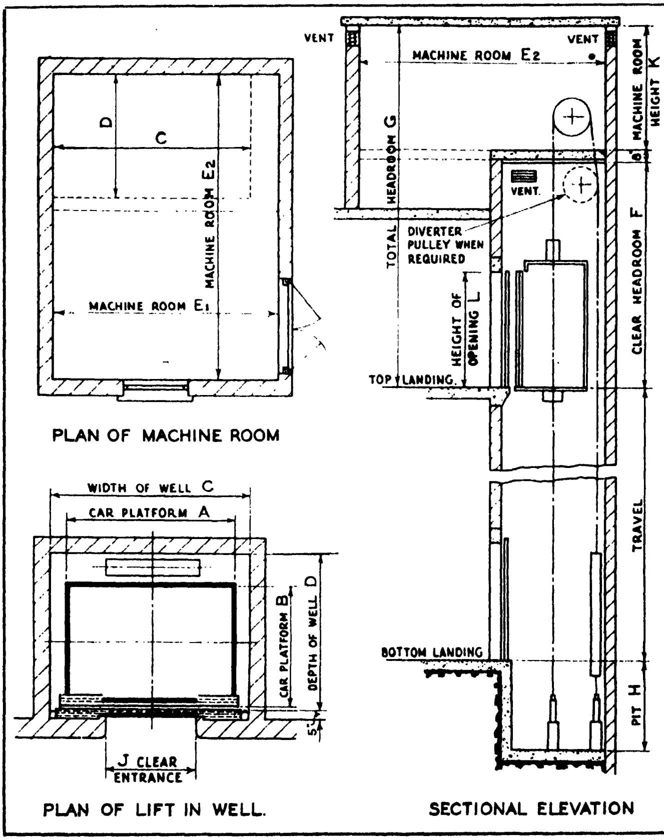

FIG. 3.—Lifts for General Office Buildings.
(To be read in conjunction with Tables 1 and 2—Page 821.)

separate lift-well adjacent to the main staircase. If the building be of sufficient height to warrant high-speed lifts it will be found generally that more than one lift will be required, in which case it will be best to arrange the two or more lifts side by side in a common well. So doing involves the advantages of providing a common machine room for all lifts, that the control of the lifts can be interconnected more conveniently, and of greater convenience in service as the landing entrances are adjacent on each floor.

In the shop or small store the lift or lifts are best sited adjacent to the main traffic aisle through the premises and need not be adjacent to the main staircase. Approach to the lifts should be

well defined and clear of obstructions. Where two or more lifts are concerned use of a common lift-well will carry similar advantages to those given above for lifts in office blocks. In the larger stores where escalators are employed the lifts will be the secondary form of vertical transport and must give pride of place in consequence. The former will lie in the main flow of traffic to and from the principal entrances, whilst the lift installation will occupy a position in the rear of the premises.

TABLE 1.

LOAD		NETT CAR AREA SQ. FT.	OUTSIDE PLATFORM		LIFT WELL		WIDTH OF ENTRANCE J
PERSONS	LBS.		WIDTH A	DEPTH B	WIDTH C	DEPTH D	
10	1500	19	6'-0"	4'-0"	7'-4"	5'-0"	3'-0"
15	2250	26	6'-9"	4'-7"	8'-1"	5'-7"	3'-6"
20	3000	33	7'-6"	5'-3"	8'-10"	6'-4"	4'-0"

These dimensions apply only to travels not exceeding 100 ft. For dimensions E, F, G, H, K, L and M, see Table 2.

TABLE 2.

LOAD												
LOAD	PERSONS		10				15			20		
	LBS		1500				2250			3000

PIT DEPTH		H	3'-3"	4'-0"	4'-0"	5'-0"	4'-0"	4'-0"	5'-0"	4'-0"	4'-0"	5'-0"
MACHINE ROOM HEIGHT (MIN.)		K	7'-0"	7'-0"	7'-0"	7'-6"	7'-0"	7'-0"	8'-0"	8'-0"	8'-0"	8'-6"
LANDING ENTRANCE HEIGHT		L	6'-0"	6'-8"	6'-8"	6'-5"	6'-8"	6'-8"	7'-0"	7'-0"	7'-0"	7'-0"

Where speed exceeds 300 ft. per min. or the travel exceeds 100 ft. the lift engineer should be consulted.

Where two lifts are adjacent the width of the lift-well will be twice dimension ' O ' (Table I) + 4 in.

(Tables to be read in conjunction with Fig. 3—Page 820.)

Number of Lifts Required.—Decision regarding the number of lifts necessary to satisfy the traffic requirements of any particular building is not easy and there are no hard and fast rules available to help. The number of goods lifts required is less difficult to establish than passenger lifts for the reason that the probable weight and bulk, total and individual, of freight items to be carried and their cycle and frequency of movement can be estimated with fair ease. The probable passenger lift traffic is less easy to estimate since it involves a number of factors which cannot be known with any degree of accuracy until the building is in use.

In the case of industrial workers' flats the number of passenger lifts required in all probability settles itself by the very grouping of the flats into their individual blocks and access services. For office blocks, the number of lifts required, and their capacity and speed, since these aspects will affect the number, is better based upon the estimated population per floor of the building than by using any fixed relation of lifts to floor areas. The effects of interfloor traffic resulting from the siting of staff canteens, lavatories, etc., on particular floors must be taken into consideration. In general it may be taken that if lift capacity is provided capable of handling the normal traffic peaks, occurring morning, mid-day and night, it will be sufficient for the other periods of the day.

In shops or small stores not provided with escalators, the number and capacity of lifts should be determined from the number of customers in the building during peak 'sale' periods. The maximum peak is likely to occur between noon and 3 P.M., and the traffic will be in both directions. A good guide to this population is obtained by allowing one person per 30 sq. ft. of net rentable floor area. The influence on traffic requirements of restaurants, demonstrations and exhibitions on upper floors must be taken into account. For the larger stores equipped with banks of escalators giving up and down service, passenger lifts become a secondary feature of the traffic problem and are needed only for those who dislike or cannot use escalators due to infirmity, or wanting to travel several floors in one journey.

Loads and Car Sizes.—No rules are possible in the case of goods lifts since both the load to be carried, and the car size and width of car opening required to accommodate it will be determined by the physical characteristics of the freight to be handled. The car size corresponding to the loads given in the Tables of figs. 4 and 5 must, therefore, be treated as suggestions requiring a check on the basis of the type of goods to be carried.

The basis for determining the rated load for passenger lifts is the average person whose weight is taken to be 150 lb. It must be taken as axiomatic that the floor area provided for a passenger lift car must not be greater than that required to accommodate the number of persons corresponding to the rated load. To do otherwise would involve the risk of overloading the equipment. It can be achieved by working to the following allowances—

For lifts rated to carry up to 10 persons (1,500 lbs.) allow 2 sq. ft. of floor area per person.

For loads in excess of this reduce this allowance to 1·75 sq. ft. per person.

Recommended Speeds.—Selection of lifting speed involves factors difficult to express as hard and fast rules. Speed, by affecting travelling time has a considerable effect upon the traffic handling capacity of a lift. Owing to the time lost loading and unloading, however, this capacity does not increase in direct proportion with increases of speed. For this reason, with a passenger lift serving a travel of 80 ft. a 100 per cent. increase in speed will have the following effect upon capacity :—

Speed increased from 150 to 300 ft. per minute—approximately 50 per cent. increase in traffic capacity.

Speed increased from 200 to 400 ft. per minute—approximately 33 per cent. increase in traffic capacity.

This disproportionate effect of speed upon capacity is even more marked in the case of goods lifts where the time occupied in loading and unloading forms a greater part of the average circular trip time than with passenger lifts. It is seldom in consequence that there is sufficient capacity advantage to be gained by operating goods lifts at more than 100 ft. per minute, except perhaps where bulk freight is trucked into and out of the lift car, and where there is sufficient traffic to warrant the use of an attendant-operated machine. In such cases speeds of 150 or 200 ft. per minute may be justified.

For passenger lifts the selection of speed must be guided by the psychological effect upon the user, who will become restive if called on to travel long distances at slow speeds, but this aspect must be related to the type of service required of the lift. Obviously, lifts normally giving floor to floor service may be operated at lower speeds than those giving terminal service.

The effect of speed upon capital cost must not be overlooked. A speed of 100 ft. per minute represents the maximum for which single-speed motor and control equipment will be suitable and ensure satisfactory levelling for passenger lifts. Even this speed is often too high for goods lifts to be similarly equipped since a higher degree of floor levelling accuracy is demanded, especially where goods are trucked into and out of the lift. For passenger lift speeds in excess of 100 ft. per minute, and goods lifts at any speed in excess of about 40–50 ft. per minute where any accuracy of floor levelling is required, some form of slowing and levelling equipment will be essential and will involve additional capital cost.

FIG. 4.—Goods Lifts for Office Buildings.—Speeds up to 100 F.P.M.

The following general recommendations on speeds for passenger lifts may be used for guidance—

(i) Selection should be made from the following standard range :—
100, 150, 200, 300, 400, 500, 600 and 700 ft. per minute.

(ii) For industrial workers' flat lifts a speed of 100 ft. per minute is recommended to ensure the use of economical equipment.

(iii) For office and similar buildings—
No of floors served, five or less—200–300 ft. per minute.
" " " six to ten—300–400 " " "
" " " more than ten—not less than 400 ft. per minute.

(iv) For shops and departmental stores—

Small establishments	150 ft. per minute.
Larger "	200–300 ft. per minute.
Large establishments provided with escalators	300–400 ft. per minute with the higher speed used for lifts giving primarily terminal service.

Types and Rating of Lift Motors.—Three-phase alternating current power now being almost universal, motors suitable for such a supply only are considered below. Lift motors are required to start against load and must, therefore, be designed to give at least twice full load torque at starting which may limit the employment of squirrel cage motors where permissible starting currents are fixed at a low figure. It is considered poor practice to use lift motors operating at more than 1,000 r.p.m. and the majority of geared traction machines operate around this figure. Unless site conditions demand otherwise lift motors will be of the screen protected type.

Until comparatively recently lift motors have been rated on the basis of the normal intermittent half or one hour ratings, the former being considered suitable for the type of lift service required in small office buildings, residential flats, etc., whilst the latter was adopted for the more intense service required in busy office buildings, departmental stores and the like. Increased use of two-speed motor equipment involving slowing and levelling conditions in addition to starting has shown previous ideas of rating to be inadequate if over-heating of motors is to be avoided. The modern conception of rating of lift motors is to adopt as a basis the number of starts per hour and to call for motors capable of handling such numbers without exceeding the limits of permissible temperature rise. The following ratings in terms of starts per hour can be taken as a representative guide—

Light duty —Below 60 starts per hour.	Intermittent service, *e.g.* goods lifts, industrial workers' flats, small office buildings.
Normal duty—Up to 120 " " "	Normal passenger lift service.
Heavy duty — " 240 " " "	Departmental stores, busy office buildings, 'under-lifted' buildings.

The types of motors in general use for lifts are :—

Single Speed Slip-ring and High Torque Squirrel Cage Induction Motors.—Suitable for use on passenger lifts operating at speeds not greater than 100 ft. per minute, and for goods lifts at similar speeds where great accuracy of floor level is not required. Use of the squirrel cage type will be limited to cases where starting currents in the region of 3½ times full load current are permitted and where the refinement of rheostatically controlled acceleration is not required.

Two-Speed High Torque Squirrel Cage Motors.—Used extensively in the three to one speed range for passenger lifts up to 200 ft. per minute and goods lifts up to 100 ft. per minute. Capable of use with direct approach forms of levelling equipment, but will give levelling accuracy equivalent only to the lower of its two speeds. Incapable of giving refined conditions of acceleration, slowing and stopping. Requires starting current of 4½–5 times full load if switched direct on high-speed winding. Where this is not possible it can be started through the slow-speed winding, but with less smooth acceleration characteristics.

Two-Speed Tandem Motors.—Its greater speed range of six to one renders this type suitable for passenger lifts up to 250 ft. per minute with both direct approach and corrective levelling to give a high degree of levelling accuracy. Starts as an ordinary slip-ring machine requiring 2½ times full load current and rheostatically controlled acceleration ensures smooth starting. Deceleration and stopping conditions are less refined than with variable voltage equipment.

Variable Voltage Equipment.—Operates on the well-known Ward Leonard principle and is suitable with a geared traction machine for passenger lifts up to 350 ft. per minute and above this speed in its gearless traction form. Useful for goods lifts in the 150–200 ft. per minute speed range where great floor levelling accuracy combined with corrective levelling is required. Can be designed for speed ranges of 25 to 1, in the geared traction types and greater ranges in the gearless. Capable of great refinements in accelerating, slowing, levelling and stopping conditions, and, therefore, employed extensively in high-class installations.

Motor Horse-powers and Consumptions.—The horse-power required for any lift will be not only a function of the load and lifting speed, but also of the overall efficiency of the machine and will,

therefore, vary a little between different makers. It will also be affected by the degree of balance provided. Theoretically the greatest economy in running cost is achieved by balancing the weight of the lift car and its sling and safety gear plus the average load carried over a period. The latter will rarely be a constant figure and it is obviously impossible to adjust the counterweight to suit it. Lifts are, therefore, normally balanced for 40 per cent. or 50 per cent. of their rated load plus the weight of the car, etc., such balancing having proved to result in the most economical operating conditions on the average installation. The following formula will give a good approximation of the b.h.p. required for a lift.

B.H.P. $= W \times S \times C$, where

W = rated load in cwts.

S = speed in ft. per minute.

C = A factor, being 0·0045 if the driving machine is above the lift-well and 0·0048 if below.

This formula assumes a 50 per cent. balance of the rated load and an overall efficiency of 36 per cent. and, therefore, is applicable to geared traction machines only.

The power consumption of electric lifts is surprisingly small and a close approximation to what it will be is given by the following formula :—

$$U = \frac{P \times k \times T}{3{,}600}$$

where U = Energy consumption in b.o.t. units for one complete circular trip, *i.e.* up and down, of the lift.

P = b.h.p. of motor.

k = A factor being 0·65 for a fully loaded trip.
0·52 „ half load trip.
0·6 „ no load trip.

T = the time in seconds for one complete circular trip is given by $\frac{L \times 60}{S}$ seconds

where L = twice the lift travel in ft.

S = speed in ft. per minute.

Control and Signal Systems.—A number of control systems designed to meet varying conditions of lift service are available. In the main they are variations or combinations of the following :—

(i) *Car-switch Control.*

A method of control whereby the movement of the car is directly under the control of the attendant by means of a switch in the lift-car.

(ii) *Automatic Push-Button Control.*

A method of control by means of buttons at the landings and in the lift-car, the momentary pressure of which will cause the lift-car to start and automatically stop at the landing corresponding to the button pressed.

(iii) *Collective Control.*

An improved form of automatic control in which calls from the lift-car and lift-landings are registered, and are answered by the lift-car stopping in floor sequence at each lift-landing for which a call has been registered, until all calls have had attention.

(iv) *Signal Control.*

A method of control in which, although the lift-car is started by means of a car-switch or button situated therein, the stops are determined and registered by the pressure of signal buttons on the various lift-landings, and by pressure of other buttons in the lift-car. With a group of lifts, the signals made by the pressure of 'up-down' landing-buttons are answered by the first available lift-car travelling in the corresponding direction.

The use of the simple forms of automatic push-button control should be limited to where the required lift service is light and intermittent, and the number of floors served small, *e.g.* small blocks of flats and offices. In all large office buildings attendant operated control is necessary, preferably of the signal control type and interconnected if batteries of two or more lifts in centralised lift-wells are involved. It is an advantage, nevertheless, for one lift in each battery to have in addition passenger control, usually of the collective type, to provide for lift service outside normal working hours. Such dual forms of control can be applied usefully wherever it is necessary to provide 24-hour lift service throughout the day, but attendant operation is needed only during certain well-defined peak periods.

The requirements of departmental store passenger lift service are usually met by some form of attendant operated control which can be one of the simpler forms for lifts operating in 150–200 ft. per minute range. Above this range floor finding and levelling should be automatic and outside the control of the attendant. This can be done by using a form of signal control simplified to suit the floor to floor service normally required in departmental stores.

The signal systems required for the intelligent and efficient operation of a lift service will vary with the type of control used. Thus they will range between the inexpensive forms of call bell annunciators or landing 'lift coming' or 'lift here' indicators associated with simple car-switch

and automatic push-button controls respectively, and the comprehensive position indicators and interconnected signal systems associated with collective and signal controls. It must be accepted that properly selected and applied a signal system is not an unnecessary luxury but an essential towards securing the maximum and most efficient service from any lift installation.

Protection of Car and Landing Entrances.—The modern tendency towards solidly enclosed lift-wells requiring fire-resisting doors to landing openings has resulted in the increasing use of solid sliding doors for both car and landing entrances. There can be no doubt these offer the best form of protection and their use is recommended wherever possible and certainly exclusively for passenger lifts. They are available in various types :—

(i) Single leaf sliding to one side.
(ii) Two leaf centre opening.
(iii) Two leaf two-speed, or three leaf three-speed opening to one side.
(iv) Four leaf comprising a pair of two leaf two-speed arranged to give opening to opposite hands from the centre.

The first two of these four types should be used wherever lift-well and car opening dimensions render them suitable. All such doors should be provided with vision panels and tracks in bronze or some other non-corrosive material.

Power Operation of Car and Landing Doors.—The serious accident hazard introduced by the practice of using moving car floors as a means of permitting unoccupied passenger operated lift-cars to be moved with gates or doors open has led to the abandoning of this device. So doing has introduced the intolerable nuisance of such lifts being put out of action by the car door being left open. It is, therefore, essential some form of closer be fitted to the car door which can be either of the spring-operated or motor-driven type, the latter being the better of the two.

Complete power operation of both car and landing doors is now becoming accepted practice and its use is justified by the improvement in lift service given.

It not only eliminates stoppages due to doors on passenger operated lifts being left open, but expedites the service given by attendant operated machines by reducing loading and unloading times. It should be noted that power operation when applied to a centre opening form of solid sliding doors, *i.e.* types (ii) and (iv) mentioned above, will be twice as efficient in respect to opening and closing times, assuming the same door speed, as if it is applied to the other two types. Power operated doors of the former types are recommended, therefore, for lifts required to give a high traffic capacity performance, *e.g.* in large office buildings and departmental stores.

Safety Equipment.—As befits a machine placed at the service of the ordinary public, a lift must be fully equipped with safety devices to prevent accidents and guard against the hazards of mechanical or electrical failures in the equipment. Such devices will include :

(i) *Safety Gears.*

Accidents due to rope failure are prevented by fitting a rope safety gear, which operates on failure and suspends the car upon its guides. For passenger lifts this safety gear must be fitted beneath the car and be operated by an overspeed governor for lifts having a travel exceeding 20 ft. It may be instantaneous in its operation for lifting speeds up to 200 ft. per minute, but above this speed must be designed to be applied gradually.

(ii) *Protection against Over-travel.*

Every lift must be provided with upper and lower normal and final stopping device. It is usual for the normal terminal stopping device to interrupt the control circuit for the direction in which the lift is moving when the device operates, and to automatically re-set itself when the lift is moved away in the opposite direction. The final terminal stopping device on the other hand once operated disconnects the machine from the supply thus preventing further movement in either direction, and is arranged for re-setting by hand.

Buffers for both the car and counterweight are provided in the pit as a final protection against the effects of over-travel. They will take the following forms :—

For lifting speeds not exceeding 75 ft. per minute . .	Buffers of timber or rubber.
" " " " " 300 " " . .	Spring buffers.
For lifting speeds exceeding 300 ft. per minute . .	Oil buffers or their equivalent.

(iii) *Locking Devices for Landing Gates or Doors.*

Every landing gate or door must be fitted with a locking device which will make it impossible for such gate or door to be opened unless the lift is in that particular landing zone and impossible under normal operation to start the lift car in motion unless all landing gates or doors are in the closed and locked position. The design of such locking devices should be such that they fail to safety and that they be tamper-proof. It is recommended that for lifts serving more than two floors at speeds in excess of 100 ft. per minute the operating ramp for landing lock be of the retiring or retractable type to prevent the opening of any landing gate or door while the car is passing through a landing zone to another. It is further recommended that such locking devices be of the pre-locking type in which the landing gate or door must be in the closed and mechanically locked position before the electrical interlock is made and the lift-car capable of being moved.

Interlocking of the car gate or door is provided for electrically only.

ESCALATORS.

Where large crowds have to be moved from one level to another, or where there is advantage in encouraging them to do so, escalators provide a better answer than do lifts. They have a passenger-carrying capacity equalled only by an excessive number of lifts. By eliminating passenger waiting time and the need for lift attendants, escalators give continuous, and therefore better, service at a lower operating cost. Their field of application has widened during recent years from that associated with railway systems into use in departmental stores, subway tunnels, factories—for bulk movement of operatives, office buildings, public exhibitions and amusement parks.

Escalators are built as self-contained units giving service in either the up or down direction between any two levels, *i.e.* simultaneous up and down service requires two units. Control equipment is provided to make them reversible at will and vertical heights of up to 100 ft. have been served by single units, although it is advisable to break down heights in excess of 50 ft. 0 in. into shorter flights. Each unit consists essentially of :—

(i) A fabricated steel truss. This truss is supported from the building fabric :—

For vertical rises up to 20 ft. 0 in.	Two or three point suspension.
" " " " " 30 ft. 0 in.	Three point suspension.
" " " above 30 ft. 0 in.	Four or more point suspension.

(ii) The continuous band of steps contained within this truss plus its associated equipment—step chains, driving end sprocket, reversing carriage, the tracks on which the steps run and by which they are constrained to take up their stepped formation and to level off at either end of the machine.

(iii) The driving unit consisting of motor, worm gear and controller. This and its associated supporting steelwork is situated normally at the head of the escalator immediately beneath the upper level served. A duplex chain drive forms the link between the driving unit and the escalator head shaft.

(iv) The moving rubber handrails and their associated chain and sprocket drive from the escalator head shaft.

(v) The balustrade casing usually decoratively styled.

Escalators are standardised as to angle of inclination and widths, as follows :—

Angle of Inclination.—This may be either 30° or 35° to the horizontal. Table 3 gives the leading dimensions for escalators of either angle and demonstrates the reduced overall length of the 35° type. The 30° angle results in a better ratio of step tread to riser and is, therefore, to be preferred whenever site conditions permit. It is suitable for any vertical rise. The 35° angle, due to its steeper slope, is not recommended for use with rises in excess of 20 ft. 0 in., but within this limit can be used with advantage in many cases owing to its reduced overall length.

TABLE 3.

α	30°	35°
A	8 ft. 4 in.	7 ft. 5 in.
B	H × 1·732	H × 1·428
C	5 ft. 6 in.	9 ft. 7 in. (C and D)
D	8 ft. 0 in.	
E	4 ft. 10 in.	5 ft. 3 in.
F	5 ft. 9 in.	5 ft. 1 in.
G	4 ft. 6 in.	3 ft. 11 in.
H	Vertical Rise	Vertical Rise
J	3 ft. 0 in.	3 ft. 0 in.
K	3 ft. 6 in.	2 ft. 9 in.
L	4 ft. 6 in.	3 ft. 11 in.
M	2 ft. 0 in., 3 ft. 0 in., 4 ft. 0 in.	2 ft. 0 in., 3 ft. 0 in.
N	4 ft. 7 in., 5 ft. 4 in., 6 ft. 2 in.	4 ft. 3 in., 5 ft. 1 in.

Note.—These dimensions will vary with different makes of escalators, but those given can be taken as generally representative of all makes.

Nominal Widths.—These are 2 ft. 0 in., 3 ft. 0 in., and 4 ft. 0 in. and refer to the width between the balustrade casings measured 24 in. above the step nose line. The clear width of step is approximately 6 in. less than these nominal widths. The 4 ft. 0 in. width is not available in the 35° angle machine. Table 3 gives the overall widths of machine corresponding to these nominal

widths. Selection of the most suitable width involves a number of factors, including that of traffic capacity required, but in practice tends to become standardised into the following :—

2 ft. 0 in. Passing into disuse except where overall width of the escalator is a deciding factor due to space limitations. Escalator will accommodate one person per step only.

3 ft. 0 in. Considered adequate for most departmental store applications. Escalator will accommodate two medium size persons per step and will permit passing except between heavily laden persons.

4 ft. 0 in. Use limited in main to railway and subway tunnel applications, but may be adopted for service between lower floors of departmental stores. Escalator will accommodate and permit passing between two heavily laden persons.

The capacity of an escalator in terms of the number of passengers it can transport in a given time is a function of both its width and the step speed. Experience has shown a speed of 90–100 ft. per minute on the incline to be suitable for most applications other than where either vertical rises in excess of 30 ft. 0 in. are involved or exceptionally large peak crowds have to be moved. The 2 ft. 0 in., 3 ft. 0 in., and 4 ft. 0 in. wide escalators will handle 4,000, 6,000 and 8,000 persons per hour respectively when operating at 90 ft. per minute.

Increasing the speed above 90 ft. per minute will increase these capacities in almost direct proportion up to an optimum of 150 ft. per minute, after which further increases have little effect owing to the inability of users to feed on to the escalator sufficiently fast for each step to be occupied as it becomes available. When considering capacity it must be borne in mind escalator service must be provided to handle peak loads over relatively short periods rather than the average over long intervals. Selection of speed must take into account the ability of users to get on and off the escalator rather than its effect upon capacity bearing in mind the purpose for which the escalator is provided—whether as a form of vertical transport people must use to save time and avoid physical exertion as with railway escalators, or, as in departmental stores, as an inducement to move from one level to another.

The horse-power required to operate escalators will vary with the vertical rise involved and the type and make of escalator employed. A rough guide can be obtained from the following empirical formula, which refers to 30° escalators operating at 90 ft. per minute.

$$\frac{0{\cdot}0109\ WH}{E}$$

where E = overall efficiency of the escalator and equal to 56–60 per cent.

W = Nominal width of escalator in inches.

H = Vertical rise in feet.

This formula gives the horse-power required to operate the escalator when fully loaded. For half and no load the power required will be about 64 per cent. and 27 per cent. respectively of this figure. Since there will be considerable periods in the normal daily life of an escalator when the passenger traffic is below the maximum capacity of the machine, the power consumed will be less than that corresponding to the horse power rating and is found in practice to be one-third to one-half of this latter figure. Motors for escalator duty are, of course, continuously rated.

Being a form of public transport it is essential that proper safeguards be provided in escalators to ensure safety to the user. In addition to designing to a high factor of safety and for minimum running clearances throughout the exposed portions of the machine, the safeguards required by various codes of practice for escalators are :—

(i) Prohibition of glass panels in balustrade casings, which are to be smooth and substantially flush throughout their length.

(ii) The track arrangements must prevent displacement of the steps and running gear if a step chain breaks.

(iii) A conspicuously marked 'Stop' push or switch accessible to the public must be fixed at the top and bottom of each escalator.

(iv) Any escalator operating in the ascending direction must be equipped with an anti-reverse device, which will interrupt the power supply and apply the main drive brake in the event of accidental reversal of direction of travel.

(v) Each escalator must be provided with an overspeed governor, which will operate and bring the escalator to rest in the event of the speed exceeding normal by 25 per cent.

(vi) Each escalator must be provided with a broken chain device, which will interrupt the power supply and apply the main drive brake in the event of one or both of the step chains breaking.

(vii) Each escalator must be provided with a main drive brake, which will automatically stop and hold the escalator when travelling or tending to travel in the descending direction should any of the above safety devices function.

Where several escalator units have to be combined into a system giving service to a series of floor levels—*e.g.* in departmental stores—a variety of layouts are possible of which a representative selection is given at fig. 6 and discussed below :—

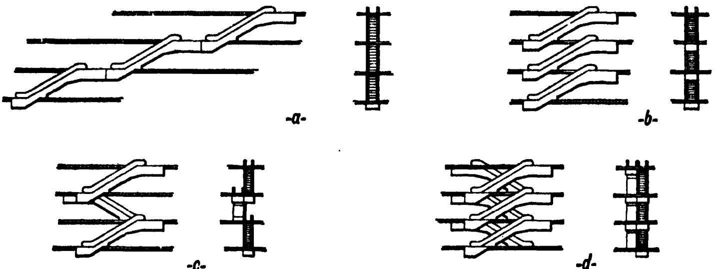

FIG. 6.

Fig. 6*a*.—Provides up or down service suitable for both interfloor service or continuous travel between lowest and highest floors without passengers needing to change direction from one flight to the next. Simultaneous service in the reverse direction will involve a similar bank of machines.

Fig. 6*b*.—Provides similar service to that given by fig. 6*a* layout. It is a more compact arrangement but has disadvantage that passengers travelling between more than two floors must reverse their direction and walk the length of one escalator between flights. Simultaneous up and down service will involve a similar bank of machines, which if placed parallel and close to the first bank will result in up and down traffic becoming confused at the upper and lower landings of each pair of escalators.

Figs. 6*c* and 6*d*.—Examples of compact arrangements to provide both interfloor and continuous travel service. Passengers pass from flight to flight with a minimum of walking. In the double corkscrew bank (fig. 6*d*) the simultaneous streams of up and down traffic are kept distinct from each other at the tops and bottoms of the escalators. These arrangements are without doubt the most suitable for departmental stores.

Fire and escape regulations imposed by Local Government authorities affect the layout and siting of escalators and need to be studied in the initial stages of any project. There is a growing tendency on the part of such authorities to demand special precautions which limit complete freedom to the planner where escalators pass through the floors of a multi-storey building and in so doing involve openings in the fire break between such floors. The expedients required to provide these precautions will vary between the extremes of either siting the escalator system in its own distinct zone, divided from the rest of the building by fire-proof partitions and automatically-controlled shutters, or relatively simple arrangements of sprinkler systems with smoke break curtain walls suspended below the floor openings through which the escalators pass.

SECTION XXXVIII

PART III

AERIAL ROPEWAYS AND BELT CONVEYORS.

AERIAL ROPEWAYS.

(*See also* SECTION XXI, PART III, VOL. I.)

Aerial Ropeways may be divided into two fundamental types:—The SINGLE ROPE or MONOCABLE, and the DOUBLE ROPE or BI-CABLE. In the first, a single endless rope is used both to support and move the loads. In the second, there are one or more supporting ropes and an endless hauling rope. Adapted to these types are the 'Fixed or Non-detachable Clip System,' on the Single Rope Type, and the 'Jig-back' or 'To-and-fro System,' which is applicable to either type.

There is considerable divergence of opinion upon the merits and demerits of the two systems, which is due largely to the fact that a number of plants have been installed without giving due consideration to which type is most applicable to the nature of ground to be traversed, and the duty to be performed.

THE SINGLE ROPE OR MONO-CABLE SYSTEM.

Ropes.

By experience, it has been found the most suitable form of rope on an average length line is a 6·7 Lang's lay, with a specially hard hemp core. On short lines when the rope is subject to a great number of bends per hour around the terminal sheaves, compound lays are sometimes used. Wire cored ropes are also occasionally employed, owing to the fact that they tend to stretch less than those with hemp cores, but they have been found by experience not to have such a long life.

On a well-constructed line, depreciation on rope is covered by ·125 pence to ·3 pence per ton mile carried, on the basis of a line not less than 1,000 yards long, and a capacity of over 25 tons per hour; as the length and capacity increases, the depreciation per ton mile carried decreases. The fact that on a single rope system the entire length of the rope is constantly passing under observation at the terminals renders it very safe against failure, and it can be worked until a comparatively low factor of safety is reached.

Loads.

When possible, individual loads should be kept to about 1 per cent. of the hourly capacity of a line, for the purpose of distributing the weight on spans. Heavy individual loads tend to increase prime costs.

Carriers and Clips.

Among the best known are Roe's Patent Toggle and Saddle Clips.

The former, fig. 1, is capable of sustaining a load at an angle of over 45°, and in theory is the most efficient of all clips actuated by the load, as the whole of the tare weight also is used

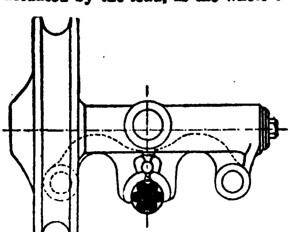

FIG. 1.

for gripping. In practice, however, the saddle clip, fig. 2, is found preferable and is usually adopted. The gripping in this type is performed by two cast chilled saddles, the sides of which

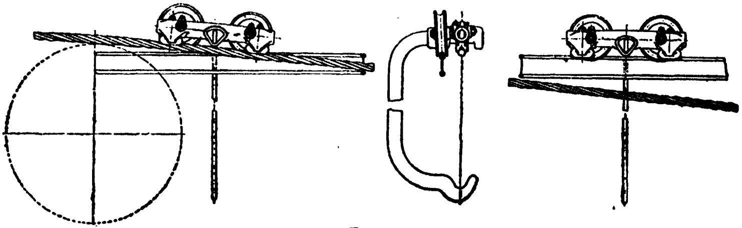

Fig. 2.

are inclined, one side having a feather projection which engages into the lay of the rope, this projection being so formed that it disengages itself without damaging the strands when the carrier enters a station. The ruling grade on which this type of clip can be safely worked is 1 in 2½. The tare weight of clip, carrier, and bucket is usually about one-third of the net load.

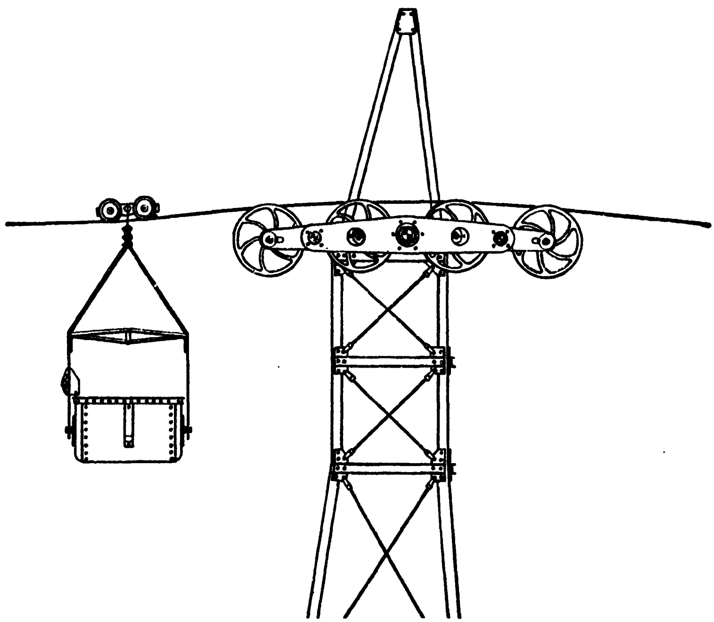

Fig. 3.

Fig. 3 shows the 'Roe Balance Beam.' The arrangement is used for distributing the pressure equally on a series of sheaves; these are arranged in groups of 2, 4, and 8. The introduction of a number of balanced sheaves in series greatly facilitates the working of long spans, and reduces wear and tear of rope where heavy pressure on any trestle has to be sustained.

A fair speed for the rope is 400 ft. per minute, though under certain conditions it can be run up to 550 ft. per minute, when no automatic return or dumping is required. The factor that rules the speed is the velocity at which the loads can be brought up to for engaging

with the rope, bearing in mind that the load and rope velocity should synchronise at the point of attachment.

Power.

Any available power can be used as long as it is steady. Trouble, however, may be caused by using intermittent power, as this gives rise to oscillation of the rope in long spans. On automatic lines, the surplus power is preferably absorbed by means of a fan or turbine. When possible, the power should be placed at the upper end of a line, and the tension at the lower terminal. In long lines that have to be sectionalised, the driving or brake station, as the case may be, is sometimes placed between two sections and the tension arrangements at the ends.

Tension

To ensure a constant and even tension, it is essential that the counterweights should be always free and floating, and owing to the amount of stretch in hemp cored ropes, taking-up gear must also be allowed for. Fig. 4 shows an arrangement which combines a multiplying and taking-up device. The two sheaves at A are attached to the tension trolley, the winch and differential drum being mounted on an independent frame placed over the tension

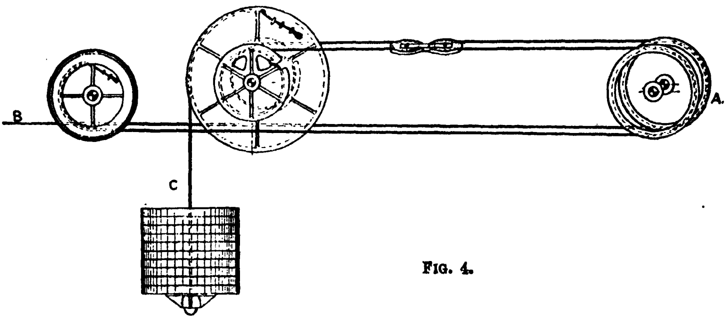

FIG. 4.

pit; one end of the rope B is anchored, the other being made fast to the tension winch drum. By this arrangement the resultant pull at A is four times the dead weight applied at C, and the weights can always be kept in suspension without the necessity of a deep pit, by taking in the slack with the winch.

Spans.

The distance between standards is dependent on the configuration of the ground, but over undulating country the average distance is approximately 330 ft. for lines of up to an hourly capacity of 60 tons. On a ropeway over the Andes, having a total length of 46 miles, several spans are being worked of 2,800 ft., though the longest recorded span on the single rope system is 3,600 ft.

DOUBLE ROPE OR BI-CABLE SYSTEM.

Carrying Ropes.

Carrying ropes may be divided into two main classes, 'spiral,' fig. 5, and 'locked coil,' fig. 6. The main advantage of the spiral type is its cheapness, and in lines transporting a small tonnag

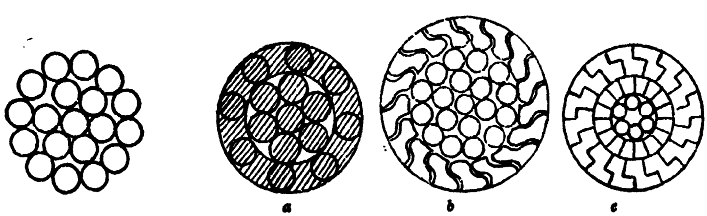

FIG. 5. FIG. 6.

per hour it will generally answer its purpose. Ropes of this type should consist of 19 wires in ropes up to 1 in. diameter and of 37 wires in ropes up to 1½ in. diameter. With this latter the

individual wires have a diameter of about ·205 in., which is about the limit to ensure perfect homogeneity of the material. Above 1¼ in. diameter, locked coil ropes should invariably be used.

Locked coil ropes, fig. 6, are of two types, the special locked, *a*, and the full locked, *b* and *c*. The former consists of a spiral core surrounded by a layer of round wires kept apart by wires drawn to a special section. This rope is sold at a medium price between plain spiral rope and full locked coil. The surface of the special locked rope is not perfectly smooth, small interstices occurring between the wires. The full locked coil, on the other hand, presents a perfectly cylindrical surface to the passage of the cars. The second type of full locked construction—shown at *c*—is particularly useful for very heavy carriers, as, owing to the rope having an inner layer of tapered section wires, the crushing and distorting effect of the load when passing over the saddles on which the rope is supported is minimised. In addition to the great advantage of offering a smooth surface to the wheels of the cars (with the result that the wires may be of a lower breaking stress than with spiral ropes), the locked coil ropes possess the great advantage that, should by any chance one of the individual wires break, it is held in place by the neighbouring wires, and does not spring from the texture of the rope, as is the case with the spiral construction. This springing of the wires is often the cause of accidents, as the cars run against the outstanding wire, and are thrown off the line.

Fixture of Ropes.

The ropes are anchored at one end of their length, and some form of tensioning device applied at the other end. This generally takes the form of a hanging weight, which may generally be from one-quarter to one-fifth of the total breaking strength of the rope. A factor of safety of 4·5 is a good medium. It has been proved that for spiral ropes a breaking stress of 95 tons per square inch, and for the locked coil ropes 65 tons per square inch, give the best results. When calculating the tension weight required, the fact must be taken into account, that should the weight be situated on a lower level than the anchorage, the weight of the rope itself acts as a tensioning factor.

For fixing the ends of the rope a satisfactory arrangement is to employ the ring wedge coupling. In this anchorage—shown in section in fig. 7—the single wires are kept apart by small nail-like

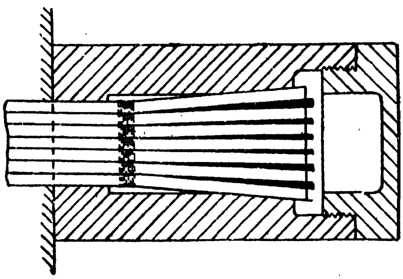

FIG. 7.

wedges, and the layers by means of ring wedges made in halves. These wedges are driven in and then a cap is screwed home, firmly locking them in place and entirely preventing any chance of the wires pulling out.

The same form of coupling, only made tapered at both ends, fig. 8, may be used for joining the various lengths of rope along the line.

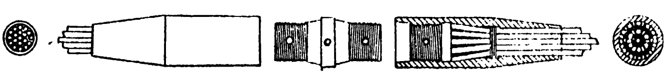

FIG. 8.

The distance apart of the tensioning weights varies according to the carrying capacity of the line, weight of carriers, number of long spans occurring, etc. A good rule is not to exceed a length of 1¼ mile between anchorage and tensioning device, although on level lines, with a small capacity, distances up to 2 miles may be taken.

Another method of tensioning is by means of buffer springs at either end of the rope, but this system is only applicable to short lines with light loads.

Diameter of Carrying Ropes.

It has been proved by experience that most trouble is caused by breaking due to bending near the saddles, and for this reason in order to obtain the diameter of the carrying rope required, many firms employ formulæ based on stresses due to bending. A formula often used is :—

$$\text{Weight per metre of ropes} = \frac{0{\cdot}85}{100}\left\{(\text{weight of carrier}) + \Big((\text{distance between carriers in metres}) \times (\text{weight of traction rope per metre}).\Big)\right\}$$

This is for spiral construction ropes. With locked coil ropes the factor 0·85 becomes 1·05. This works well for small lines up to about 50 tons capacity hourly. For each additional 5 tons, 0·05 should be added to the factor 0·85. The following table shows the various diameters of a special locked rope for various loads and traction ropes :—

(Two-Wheeled Carriages.)

Dia. of Hauling Rope.	Weight of Loads in Cwts. 3	4	5	6	8	10	16	20	24	28

$\frac{7}{8}$	—	—	$1\frac{3}{16}$	$1\frac{3}{16}$	$1\frac{5}{16}$	$1\frac{3}{8}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{7}{8}$	2

Design of Ropeway.

To lay out the profile for a ropeway, when the line is laid out on paper, the curve of the rope may be obtained and set out from the formula—

$$\text{Dip} = L^2W/8T,$$

where,

L = span; W = weight per unit length; 8 = constant; T = tension.

and then the supporting trestles placed accordingly. It sometimes happens, however, in practice that when the rope is fully tensioned it 'floats' or rises up from the supporting tower, owing perhaps to a minute error in the drawn profile. To avoid this, some Continental makers employ a so-called factor of safety for the dip—that is, the denominator 8T is multiplied by a constant —the formula giving, as a result, a dip smaller than the actual. It will be obvious that if the curve with the dip so obtained is set out and the trestles drawn up to it, they will be slightly higher than need actually be the case, thus avoiding any possibility of 'floating' when the line is erected. This factor of safety may be 1·5 for spiral ropes and 1·1 for locked coil ropes.

There has been of late years an increasing tendency to employ saddles (upon which the rope is supported at the trestles) which are pivoted at the centre, and can consequently adapt themselves to the varying gradients of the rope, and there is little doubt that this type when properly designed, and well greased to allow of play in the rope, gives full satisfaction. In designing the shoes a good medium value for the pressure of the rope is 250 lbs. pressure per square inch of projected area of the rope. This is for locked coil ropes; for spiral ropes a little less should be taken.

It sometimes happens that at a trestle, on either side of which are long free spans, there is a heavy downward reaction of the hauling rope, which, when the carrier passes over the saddle, produces a heavier pressure on the rope than that for which it was calculated. In this case the rope is protected by means of a steel plate cap over which the carrier runs, thereby removing the pressure from the rope. There is a difference of opinion as to when these caps should be employed, but it may safely be said that their use is to be recommended where the hauling rope reaction exceeds 450 lbs.

Hauling Ropes.

The *traction* or *hauling rope*, by means of which the carriers are propelled, is invariably a stranded rope with a hemp core, the flexibility depending on the size of the individual wires in the strands and the breaking stress of the material. This rope is endless and in constant motion. In the general case it passes round a driving sheave at one end of the line and round a surging or tension sheave at the other end. In some cases this plan may be varied, as, for instance, when the carriers are required to pass automatically round a large sheave at one end

station. In this case no manual attention is required at this station and the driving and tensioning sheaves are combined in the station at the opposite end of the line. Whenever possible the driving should take place at the upper and the tensioning at the lower end of the line. In this way the accumulative tension in the rope due to its own weight is utilised as a tensioning agent, whereas, were the tensioning to take place at the upper end, an additional amount of weight would be required to counterbalance the weight of the rope. The amount of the tensioning weight should be such as to give sufficient grip round the driving sheave to ensure perfect driving when the full load is on the line.

Diameter of Hauling Ropes.

The diameter of the hauling rope depends upon the highest tension occurring in it

$$\text{Tension of rope in lbs.} = \left\{\text{Initial tension} + \left(\frac{W}{S} \times H\right) + (w \times H)\right)\right\} + \left\{(W \times \mu_1 \times N) + (L \times \mu_2 \times w) + (R \times 2)\right\},$$

where,

W = weight of full carrier; S = spacing of carriers in feet; H = difference in level between stations in feet; w = weight per foot of traction rope; μ_1 = coefficient of friction of cars; μ_2 = coefficient of friction of traction rope; L = length of line in feet; N = number of carriers on one side of line; R = number of supporting rollers on one side of line.

This tension if multiplied by the factor of safety—6 to 8—and divided by the breaking stress, gives the area of the rope necessary. This is for the general case with the drive at the upper terminal and the loads ascending. When the loads are descending, the plus sign in the centre of the formula becomes minus. To obtain the tension when the ropeway is just put into work, the second half of the formula should be doubled.

The usual breaking stresses of traction ropes are from 80 to 115 tons per square inch. The surge of the hauling rope tension sheave depends upon the distance apart of the carriers, whether long spans occur in the line, etc. As an average, 6 ft. play may be allowed for to commence with, and then an additional 12 ft. for each mile of length. In some cases in long lines it is necessary to split up the line into sections to avoid excessive tensions occurring.

Driving Power.

$$\text{Power in ft. lbs.} = \left\{\left(W_1 \times W_2 \times \mu_1 \times \frac{N}{2} \times V\right) + (w \times 2L \times \mu_2 \times V) + (2R \times V) + (F)\right\} + \text{ or } - \text{ theoretical power,}$$

where,

W_1 = weight of full carrier; W_2 = weight of empty carrier; μ_1 = coefficient of friction for cars; N = total number of cars on line; V = velocity in feet per minute of cars; w = weight per foot of traction rope; L = length of line in feet; μ_2 = coefficient of friction for traction rope; R = number of supporting pulleys; F = power required for station friction.

The first four factors give the power necessary to overcome friction, and the theoretical power required or developed depends upon whether the loads are ascending or descending. The factor for station friction varies greatly for different lines, and is solely a matter of experience, although 0·02 of the total weight of the moving parts on the stations multiplied by the speed may be taken as a good mean.

Carriers.

There are two kinds of carriers in general use, those employing screw grips and those with lever grips. These may again be divided into sections, the overtype and the undertype grips. In the former, the hauling rope is attached to the carrier or running head at a point above, and in the latter at a point below the carrying rope.

The main advantage of the overtype grip is that the length of the stations is shorter than with the undertype grip, as the hauling rope may be led in and out of the jaws without interfering with the shunt rails. In the case of lever grips the overtype is generally the cheaper, and on lines containing no steep gradients can often be employed with advantage. Further, it may be more easily adapted for taking curves in both directions than the undertype. The overtype grip has, however, several great disadvantages. Chief amongst these is the fact that when ascending steep gradients the traction rope reaction falls outside the wheel base, tending to tip the whole running head, a tendency which may not be counterbalanced by the weight of the carrier, with the consequence that the whole apparatus leaves the line. Again, owing to the fact that the centre line of the hauling rope must fall outside the centre line of the carrying rope to avoid any entangling, there is a decided tendency for the carrier to tip sideways as soon as a heavy hauling rope reaction occurs, a tendency which is very detrimental to the perfect working of the line when it is required to discharge the contents of the carrier automatically whilst the carriage is on the open track. These defects may be remedied by having the hauling rope directly below the carrying rope, *i.e.*, using an undertype grip. Practically the only defect

of this type is that the stations are generally longer than with the overtype grip, thus involving extra structural work. Even this may be overcome by employing an undertype grip in which the jaws open downwards instead of upwards, as is usual.

The speed at which the carriers should be run depends upon whether it is necessary for them to be hauled automatically round curve or return sheaves by the traction rope. The following figures represent good practice :—

Straight lines	400–450 ft. p.m.
Curves up to about 45° change of direction	Undertype up to 400 ft. p.m. Overtype „ 300 ft. p.m.
With automatic haul-round—	
Sheave, 20 ft. dia.	Undertype, 350 ft. p.m. Overtype, 300 ft. p.m.
Sheave, 16 ft. dia.	Undertype, 300 ft. p.m. Overtype, 250 ft. p.m.
Sheave, 12 ft. dia.	Undertype, 200 ft. p.m. Overtype, 150 ft. p.m.

The running wheels should be of high quality cast steel, the diameter depending on the load and type of rope, larger diameter wheels being employed with spiral ropes than with locked coil. The runner pins should be self-oiling. The following table gives some diameters of wheels for varying loads, carriers with two wheels being employed :—

Weight of load and carrier, cwts.	Diameter of wheel, ins.
14	8
30	10
40	12

Screw Grips.

There are two distinct main classes of screw grip, in the first of which the grip is operated by a lever and strikers in the stations. In the second the grip is operated by the weight of the carrier and load. The best example of the former is shown in fig. 9. There are two jaws—(*a*) the movable and (*b*) the fixed. The movable jaw is actuated by a shaft carrying two screws, one a rapid thread and the other a fine thread. This shaft is turned by the lever C. The action of the grip is as follows :—On the lever C being turned over, the rapid thread operates and the movable jaw quickly approaches the fixed jaw until the rope is just gripped. The fine thread now comes into action and applies the necessary force to grip the rope firmly. To unlock the

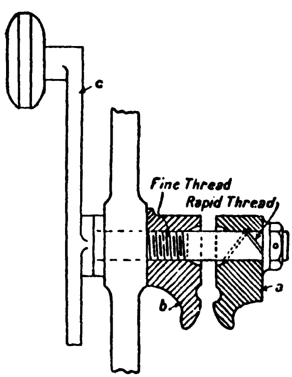

FIG. 9.

grip the reverse action takes place. The lever C is actuated at the stations by strikers constructed of angle irons.

In the other form of screw grip, in which the pressure is obtained from the weight of the carrier and load, the action is the same, the necessary turning moment being applied to the screw by hanging the carrier at the end of the lever arm. The grip is opened to allow of the rope entering or leaving, by means of rails, generally formed of angle irons, which depress small pulleys fixed at the end of the lever arm opposite to that on which the carrier is hung, thus raising the latter and thereby opening the jaws. It has been found in practice that the position of this lever arm should not be less than 35° to 40° to the vertical, to allow of easy depression of the rollers.

Lever Grips.

One of the best known Continental types is that shown in fig. 10. In this grip the pressure is applied by the weight of the carrier and load acting through a simple system of levers to give a multiplied pressure on the jaws. The grip is released by lifting the load, which is accomplished by means of small rollers running on to rails in the stations. Another type of grip—the

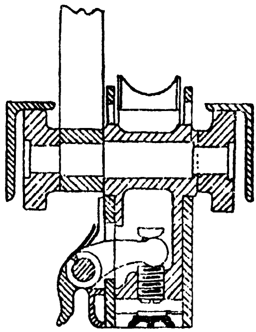

FIG. 10.

inclined plane type—is illustrated in fig. 11. The carrier and load are attached to a hanger having at its upper end a curved slot. This slot engages with a circular pin attached to the movable jaw. The downward pull of the hanger draws in this pin and with it the movable jaw, thus closing it upon the rope. When the pin is in the upper part of the slot the grip is absolutely locked, as no amount of upward pull of the rope can force the jaws apart. The grip is released

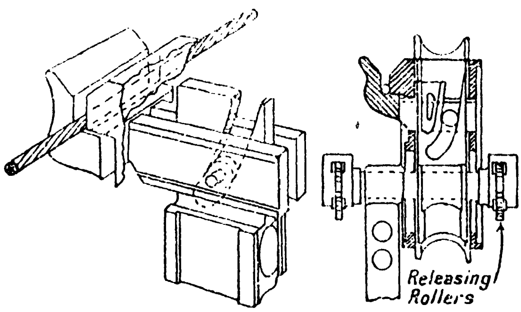

FIG. 11.

in the stations in the same manner as the type shown in fig. 10. In practice this form of grip has been found extremely simple and efficient.

In the matter of taking curves automatically in both directions, the advantage lies with the lever type of grip. In cost the latter generally has a great advantage. A ropeway, with lever grips, carrying two-ton loads on an incline of 86 per cent., is being used for carrying timber in South-West Africa.

FIXED CLIP SINGLE ROPE SYSTEM.

This type of ropeway is only applicable for light capacities, and is used largely on plantations and for the transport of valuable ores, where comparatively small quantities are handled.

The carrier head, fig. 12, is permanently attached to the rope by means of a spring steel strap, and is designed in such a way that it can pass freely over trestle sheaves, under depression wheels and round the terminals, without being detached from the rope. As both rope and carriers are in constant motion, loading has to be done by hand, or by means of a travelling hopper, which is usually hung from overhead rails at the terminal. The terminals are extremely simple and

compact, as all shunt rails are done away with. The tension terminal is usually mounted on a trolley or on skids, the whole being movable by means of tension gear, to allow for stretch of rope, etc. Angles can be worked with the fixed clip system, but they should be preferably avoided, as they tend to produce excessive rope and gear wear at such places.

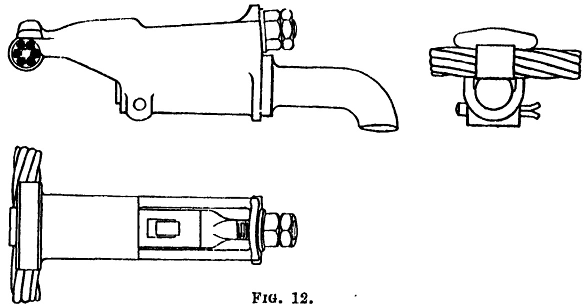

FIG. 12.

This type of line is run at a slow speed, namely, about 200 ft. per minute, and the only advantages it can claim are its simplicity, adaptability to steep grades, and its low prime cost when light capacities and moderate lengths have to be dealt with.

JIG-BACK OR TO-AND-FRO.

This type of ropeway is useful for short distances, and is operated with a pair of carriers that travel in reverse directions and are loaded or brought to rest alternatively at the opposite stations, but which do not pass round the terminals; it is, therefore, intermittent in its action, and the direction of travel is reversed after each journey. Where loads are to be carried which are heavy individually in relation to the capacity, and where the distance is short, the 'To-and-Fro System' is particularly applicable. A high carrier and rope velocity may be adopted during the run, especially where a clear span occurs between terminals, and where there are no intermediate trestles, These installations may be on the 'Monocable' or 'Bi-cable' principle, and in either case the moving rope is clamped to the carriers, and is not usually disconnected from them at the terminals.

It should be mentioned that, up to the present, the 'To-and-Fro' ropeway is the only system that is used for regular passenger traffic, as the carriers lend themselves to the adoption of a safety grip used in conjunction with an auxiliary standing rope, but with such appliances these installations are very costly and present mechanical difficulties on lines of any length.

The following table, giving a rough idea of the capabilities of the various systems mentioned, shows the maximum lengths, capacities, and loads carried on various lines at present working or in course of construction:

System.	Present Maximum Lengths.	Present Maximum Hourly Capacity.	Present Maximum Individual Load.
	Yards.	Tons.	Tons.
Monocable .	80,196	200	$1\frac{1}{2}$
Bi-cable .	38,800	250	2
Fixed Clip .	2,330	8	4 cwts.
To-and-Fro .	1,850	Passengers' weight unknown.	17 tons.

LIMITATIONS OF TYPES OF AERIAL ROPEWAYS.

The *jig-back* type is the cheapest for short distances and a capacity of 8 to 12 tons per hour. Where the distance is considerable the loss of time in making the double journey between each load is too great, and where individual loads are heavy and the speed high too much time and energy is lost in starting and stopping.

The *monocable* type is suitable for a capacity up to 80 or 100 tons per hour where the grade of the rope is not steeper than 1 in $2\frac{1}{2}$ or 1 in $2\frac{1}{4}$. Where the rope grade would be steeper than this the boxhead clips would be liable to slip on the rope, and a bi-cable would have to be considered.

The *bi-cable* type is required for steep grades and large hourly capacity. It is evident from general principles that if the number and weight of the individual loads carried by a rope be gradually increased the tension and weight of the rope will have to be increased also, and at last

a point will be reached when it is cheaper to fix the heavy main rope and use it for carrying purposes only and to provide an extra and lighter rope for hauling the loads. This point marks the natural transition from monocable to bi-cable.

CONVEYORS.

Belt Conveyors.*

For conveying materials continuously over long distances in a horizontal or inclined direction band conveyors are usually employed.

This type of conveyor consists of an endless belt running over terminal pulleys and supported at intervals both on the loaded and the return strands by intermediate idler rollers and with suitable arrangements to maintain the belt at its correct tension.

The belts are sometimes made to run flat, but more generally they are troughed on the loaded side, the effect of the troughing being to greatly increase the capacity.

The material is discharged over the head pulley or it may be discharged at any point throughout the length of the conveyor by means of throw-off carriages, either fixed or travelling, and in the case of flat belts the material may be thrown off by means of travelling or fixed ploughs.

Design Data.

Before designing any belt conveyor the necessary basic data consists of a complete knowledge of the nature of the material, the quantity to be handled, and the relative positions of the points from and to which the material is to be conveyed. The source of power available, space, etc., must also be known. A narrow belt at high speed, or a wide belt at a slower speed may be selected, either of which will give the required capacity. The initial cost of the belt, idlers, and driving unit will usually favour the narrow belt running at high speed, but there are limits, both as to speed and width, precluding the general use of high-speed narrow belts.

Factors governing the size and speed of belt are as follows: the influence of lump size on belt width; the influence of belt tension on belt width; the influence of belt speed on loading; the influence of belt speed on discharge; and the influence of belt speed on the belt life.

Capacity of Belt Conveyors.

Knowing the weight per cu. ft. and size and percentage of lumps in the material to be handled, the width and speed of belt to give any desired capacity may be calculated. It has been found from experience that the most satisfactory loading for troughed belts is obtained when the cross sectional area of the load on the belt is equal to $0 \cdot 084 \times (\text{width of belt in inches})^2$, *i.e.* $0 \cdot 084\ W^2$ = sq. ins. Assuming the belt be loaded to a cross sectional area equal to the above, the capacity in cu. ft. per hour carried at a belt speed of 100 ft. per min., will be equal to

$$0 \cdot 084 \frac{(\text{width of belt in inches})^2}{144} \times 100 \times 60 = 3 \cdot 5\ W^2 \text{ for troughed belts.}$$

For flat belts the capacity may be taken as $1 \cdot 5\ W^2$ in cu. ft. per hour at a belt speed of 100 ft. per min.

The capacity in tons per hour for any material weighing M lbs. per cu. ft. may be calculated for troughed and flat belts as follows:—

Capacity of troughed belt. $T = \dfrac{3 \cdot 5\ W^2 \times M \times S}{2{,}240 \times 100}$

Capacity of flat belt. $T = \dfrac{1 \cdot 5\ W^2 \times M \times S}{2{,}240 \times 100}$

where T = Capacity in tons per hour.
W = Width of belt in inches.
S = Speed of belt in feet per minute.
M = Weight of material in lbs. per cubic foot.

Table I gives the carrying capacity for troughed belt conveyors of various belt widths at a belt speed of 100 ft./min., calculated from the formula given. To find the width and speed of belt for a troughed belt conveyor to handle 400 tons per hour of unsized coal containing lumps of 12 in. maximum size: select from the table the minimum size of belt that will carry the maximum size of lumps. This will be found to be 30 in. for unsized material.

From the table also it will be seen that this size of belt will have a capacity of 70 tons per hour for each 100 ft. per min. of the belt speed. The speed of the belt to give the required output would therefore be $\dfrac{400 \times 100}{70} = 570$ ft. per min.

Although this speed comes within the safe maximum speed given in Table I, it is considered too high for the class of material being handled. The next size of belt available is 36 in. wide

* For much of this information we are indebted to the New Conveyor Co. Ltd.

TABLE I.

CAPACITY CHART FOR TROUGHED BELT CONVEYORS.

Size of Belt.	Maximum Size of Lumps.		Max. Recommended Belt Speed.	Capacity in Cu. Ft./Hour.		Capacity in Tons per Hour.							
						Material at 50 lb./cu. ft.		Material at 75 lb./cu. ft.		Material at 100 lb./cu. ft.		Material at 125 lb./cu. ft.

28	6	10	550	2,750	15,100	60	340	90	500	120	672	150	840
30	7	12	650	3,150	20,500	70	460	105	685	140	915	175	1,140
36	8	15	650	4,500	29,500	100	660	150	990	200	1,320	250	1,650
42	10	18	750	6,200	46,300	135	1,035	205	1,550	275	2,070	340	2,600
48	12	20	750	8,100	60,500	180	1,350	270	2,025	360	2,700	450	3,375

and to handle 400 tons per hour would have to run at $\frac{400 \times 100}{100} = 400$ ft. per min. This is considered a reasonable speed, and could safely be adopted. If, however, the coal being handled should be of a particularly friable nature, and it is important for the installation that a minimum of breakage should be obtained, it would be necessary to consider the use of a 42-in. belt running at $\frac{400 \times 100}{135} = 295$ ft. per min.

The h.p. required to drive a conveyor will depend on capacity, size, speed of belt, length, efficiency of driving gear, and type of idler rollers used. If the conveyor is inclined the h.p. will also depend on the height to which the material has to be elevated.

The length of a conveyor has a big influence on the h.p. irrespective of the load carried, because a percentage of the total power is absorbed by friction in the head and tail pulleys. A table of constants for various lengths of conveyors is given in Table II below.

TABLE II.

Speed Factors.		Length Factors.		Length Factors.	
Width of Belt. W (Ins.).	Speed Factor. C.	Length of Conveyor. L (Ft.).	Length Factor. F.	Length of Conveyor. L (Ft.).	Length Factor. F.
12	0·0133	20	2	150	1·133
14	0·0206	25	1·8	200	1·1
16	0·0277	30	1·67	250	1·08
18	0·0350	35	1·57	300	1·067
20	0·0423	40	1·5	350	1·057
22	0·0495	45	1·445	400	1·05
24	0·0570	50	1·4	500	1·04
28	0·0713	60	1·33	600	1·033
30	0·0785	70	1·286	700	1·029
36	0·1000	80	1·25	800	1·025
42	0·1220	90	1·22	900	1·022
48	0·1440	100	1·2	1,000	1·02

These values are equal to $1 + \frac{20}{\text{length of conveyor in feet}}$ and represent the length factor F in the belt conveyor h.p. formula given below.

The Influence of Speed of Belt on H.P.

The h.p. is also influenced by the speed of the belt. This is due to the friction of the idler bearings which varies in proportion to speed and type of bearings. A Table of Constants is given in Table II.

These values have been found by experience, and represent the speed factor C in the h.p. formula. The h.p. of a horizontal belt conveyor may be calculated by the following formula:

$$\text{H.P.} = \frac{(CS + DT)\ L\ F\ B}{1{,}000\ G} + 10 \text{ per cent. for contingencies}$$

where C = Speed factor (given in Table II).
D = Load factor = 0·0757.
L = Length of conveyor in feet.
F = Length factor = $1 + \frac{20}{\text{length of conveyor in feet}}$ or from table.
B = Idler co-efficient = 0·7 for ball bearings.
= 1 for journal bearings.
G = Efficiency of driving gear.
S = Speed of belt in feet per minute.
T = Capacity in tons per hour.
H = Height of lift in feet.

If the conveyor is inclined the power required to elevate the material to the desired height must be added to the power that would be necessary if the conveyor were horizontal instead of inclined.

The h.p. for an inclined belt conveyor may, therefore, be calculated by the following formula:—

$$\text{H.P.} = \left[\frac{(CS + DT) \times LB}{1{,}000} + \frac{HT}{884}\right] \frac{F}{G} + 10 \text{ per cent. for contingencies.}$$

Angle of Inclination.

The maximum gradient on which material can be carried on a belt without rolling or slipping back is governed by the shape, size, and assortment of the material, the speed, the feed on to the belt, and whether loading is continuous, or intermittent. Definite figures cannot be given to meet all requirements, but the figures given in Table III may be taken as a rough guide. The figures given are for a continuous feed and a well filled belt.

TABLE III.—MAXIMUM RECOMMENDED ANGLE OF INCLINE OF BELT CONVEYORS FOR VARIOUS MATERIALS.

Material.	Angle of Gradient in Degrees.	Material.	Angle of Gradient in Degrees.
COAL.		SAND.

PEBBLES.			
Or similar round material	12		

Belt Tension.

In order that the driving pulley may obtain a grip on the belt sufficient to drive the conveyor, a certain amount of initial tension must be applied to the belt by means of a tensioning gear. To drive a conveyor additional tension must be applied to the carrying side of the belt through the medium of the driving pulley. This additional tension may be termed the effective tension or h.p. pull representing the actual force required to move the load.

With the conveyor in operation, the tension in the carrying or tight side of the belt is the tension T_1, which is equal to the initial tension T_2, plus the effective tension of h.p. pull, while the tension in the return or slack side of the belt is equal to the initial tension T_2. The effective tension is, therefore, equal to $(T_1 - T_2)$, and is dependent upon the maximum tension of the belt, the angle of belt wrap and the co-efficient of friction between the belt and the pulley. Ratio factors for $\frac{T_1}{T_1 - T_2}$ for various type of drives are given in Table IV below.

TABLE IV.

Type of Drive.	Angle of Belt Wrap in Degrees.	Ratio of Belt Tension. Ratio $\frac{T_1}{T_1 - T_2}$. Bare Pulley.	Ratio of Belt Tension. Ratio $\frac{T_1}{T_1 - T_2}$. Lagged Pulley.
Open	180	1·84	1·5
Snub	210	1·67	1·38
Tandem	420	1·19	1·08

Number of Plies required for Belt.

If the power width and speed of belt is known, the number of plies required for the belt may be calculated as follows :—

$$N = \frac{H.P. \times 33{,}000 \times R}{S \times W \times fs}$$

where N = Number of plies of belt.
$H.P.$ = H.P. to drive conveyor.
R = Ratio of $\frac{T_1}{T_1 - T_2}$ see table above.
S = Speed of belt in feet per minute.
W = Width of belt in inches.
fs = Safe stress allowable per ply per inch of belt, according to quality of duck.

This equals :

25 lbs. per inch of ply for 28 oz. duck	British Standard
27 " " " " 32 " "	Specification
30 " " " " 36 " "	No. 490.

The Belt and Cover.

Conveyor belts are constructed to fulfil two requirements, namely strength to transmit the drive, and durability against abrasion due to the material, and also the friction of the driving pulleys. Strength is governed by the number of plies or layers, and the weight of the duck used. In order that the belt may trough properly, the number of plies must be kept within certain limits, which vary with the width of belt.

In order to give the belt more durability against wear due to the friction of the driving pulley and against the wear caused by the friction and abrasion due to the material carried, the belt is protected by a covering of rubber. This covering is $\frac{1}{32}$ in. thick minimum in the driving side, but varies in thickness on the carrying side to suit the nature of the material to be carried, and belts are available with the following thickness of top cover—$\frac{1}{32}$ in., $\frac{1}{16}$ in., $\frac{3}{32}$ in., $\frac{1}{8}$ in. and $\frac{3}{16}$ in. thick, all of which may be obtained in either Grade 'A,' 'B' or 'C' rubber in accordance with British Standard Specification No. 490.

Special heat-resisting conveyor belts are available for carrying hot materials, such as coke, cement clinkers and hot ash, the temperature, however, should not exceed 230° F.

Selection of Pulley Size.

The diameter of the terminal pulleys for good service should be as large as possible. General practice is to make the diameter in inches of all driving pulleys five times the number of plies, and tail pulleys four times the number of plies. The diameter in inches for snub and bend pulleys should be three times the number of plies. It is recommended that the faces of the pulley should also be at least 2 in. wider than the belt for belts up to 24 in. and 3 in. to 4 in. wider for larger belts. In order to increase the tractive effort of the driving pulley on the belt, the pulley may be covered or lagged with rubber. The driving pulley for the belt should be arranged wherever possible at the delivery end of the conveyor.

Several methods are available for obtaining the maximum driving efficiency from the driving pulley. In short and medium length conveyors, the drive pulleys get sufficient traction by using a plain open drive. Longer conveyors require greater effective belt tension which may be obtained by increasing the initial or slack side tension ; lagging the plain driving pulley with a covering of rubber or other suitable material ; using a snub pulley to increase the arc of driving contact ; or by using a tandem or two-pulley drive which increases the arc of contact still further.

Loading the Belt.

In order to ensure efficient working of any belt conveyor it is essential that the belt be uniformly loaded and that a minimum of wear is caused to the belt by abrasion. This is a feature which is governed by many factors, and the design of feed chutes and the provision of feeders will depend on the class of the material to be handled, and also the conditions of service required. The design and slope of the chute is of the greatest importance in order that the speed or flow of the material be given a velocity approximate to that of the belt, thereby reducing the abrasion and friction on the belt cover.

Legal.

DEFINITIONS OF MINERALS AND MINES.

By the term 'mineral,' as used in legal documents, is meant a constituent of the earth's crust which possesses in its severed condition an intrinsic value by virtue of its composition, that is to say, 'any substance that can be got from within the surface of the earth which possesses a value in use apart from its mere possession of bulk and weight' (Lord Fletcher Moulton, Court of Appeal, Nov. 23, 1908). The meaning of the word 'mineral' may be affected by the context; according to Lord Halsbury, in 'a grant of *mines* and *minerals*,' it 'is a question of fact what these words meant in the vernacular of the mining world, the commercial world and landowners at the time when they were used in the instrument' (Lord Provost of Glasgow *v.* Fairie, 13 App. Cas. 1888).

In this country a *mine* is defined as a working for mineral carried on by artificial light without intentionally disturbing the surface, whilst a *quarry* is an excavation for the extraction of mineral open to the day; the distinction is important from a legal point of view. It must be noted that a quarry less than 20 feet deep is by law classed as a factory. In many other countries, notably in the United States of America, the distinction between a 'mine' and a 'quarry' depends not upon the method of working but upon the mineral wrought, any working for e.g. building stone, whether underground or open, being classed as a quarry. In legal instruments 'mine' sometimes has the wider meaning of the space containing the minerals, or even from which the minerals have been extracted.

Ownership of Minerals.

The tenant in fee simple or 'owner' of land is deemed to own everything over, on, or under the surface down to the centre of the earth between verticals drawn upwards and downwards from the boundaries of his surface, and until recently, the only exceptions that existed to this *prima facie* right (apart from special custom) were those of gold and silver which are excepted in favour of the Crown. Now, however, since July 1, 1942, all coal, with certain associated minerals (*e.g.* interstratified ironstones and fire clays) has passed from private ownership, and under the provisions of the Coal Act of 1938 become the property of the State; a Coal Commission having been appointed by Government to exercise the functions of owners of the fee simple in coal and mines

of coal, but they shall not themselves engage in the business of coal mining or carry on any operations for coal-mining purposes, other than searching for and boring for coal, but shall grant leases for those purposes.

The department of State under which the Coal Commission exercises authority is the Board of Trade.

Compensation awarded to late owners of Coal and Associated Minerals.—A 'global' sum of £66,450,000 was decided upon as the amount of the compensation to be awarded by Government to the owners of coal in Great Britain, which sum was divided by the Central Valuation Board so as to be allocated as follows:—

The Scottish Valuation Region	£8,512,245
„ Northern „ „	13,515,930
„ Western „ „	5,409,030
„ Yorkshire „ „	10,306,395
„ North Midland Valuation Region	6,645,000
„ „ Staffordshire „ „	1,315,710
„ East Midland Valuation Region	1,475,190
„ West „ „ „	1,628,025
„ South Wales „ „	16,446,375
„ Southern „ „	1,196,100
	£66,450,000

The work of valuing the various holdings was entrusted to bodies of experts constituting the several region valuation boards named as above.

The '*valuation*' *date* was the first day of January, 1939, and the work of valuation had to be completed by July 1, 1942, the *acquistion date*, but as a matter of fact, owing to the intervention of the war, was not concluded until a year later.

As it now falls to the Coal Commissioners to exercise the functions previously possessed by the agents of many coal owners, it is to be presumed that not only will the colliery leases be simplified in structure but will tend more or less to follow a standardized form. Certainly the number of leases will be greatly reduced.

Certain requirements which existed in the past will, however, continue to operate in the future, some of these may be briefly referred to.

Certain Rent.—The right to work the coal is conceded in return for what is termed a *certain fixed* or *dead* rent of so much per annum, which merges into the *royalty* rent. The amount of the certain rent being commonly determined by the capability of working an agreed minimum number of tons of coal per annum at an agreed tonnage rate. The rent usually averages in normal cases from £1 to £1 15*s*. per acre of surface. Of course, the thickness of the seam worked is an important factor in the case.

'*Overs*' *and* '*Shorts*.'—The full amount of the certain rent is payable whatever the quantity of coal worked in any given year may be. When in any year the number of tons worked at this rent exceeds in value the certain rent, the surplus is paid as '*over workings*,' that is, chargable with *royalty rent*; when it falls short, the deficiency is carried forward as '*short workings*' to next year's account. Power is usually—nearly always—granted to the lessee to make up 'shorts' —that is, set them against subsequent 'overs'—within, it may be, a given period of years.

Royalty Rent.—The royalty in which the certain rent 'merges' is usually payable:—

(*a*) as a fixed sum per ton raised;
(*b*) as a fixed sum per foot per acre worked;
(*c*) as a fixed proportion of the value of the mineral raised;
(*d*) by way of a sliding scale;
(*e*) as a varying proportion of the value of the mineral sold, regulated as a sliding scale.

It is usual to make a final deduction from the saleable output of coal for coal used for *colliery consumption*. The amount varied in regard to past leases, but usually was 4 per cent.

The average of the 'royalties' inclusive of '*way-leaves*' payable per ton of coal raised over the United Kingdom, by whatever method payable, was estimated by the Royal Commission on Mining Royalties in 1889 to be 5·44*d*. per ton of coal worked inclusive of way-leaves, and as the way-leaves may be taken as averaging about ¼*d*. per ton, the average of the actual royalty rent would be 5¼*d*. per ton.

Way-leaves.—Way-leaves are divisible into:

(*a*) surface; (*b*) underground,

and imports the leave or permission of the owner of the property through or over which passage is required. The expression is applied usually, if not exclusively, to mining roads or ways, or shafts (*shaft rent*) for the passage of minerals, or for other mining purposes.

It is to be presumed that in so far as underground way-leaves and shaft rents (in the few cases where the latter have been charged by former lessors) now that the ownership of the coal is vested in a single lessor—the State—that these will cease to be chargeable against the lessee.

Coal Contents of a Seam of Coal.—In estimating the coal contents of a given area of a seam it is customary to take an acre as containing 1,510 tons per foot of thickness, and making deduction therefrom for loss of coal in working, the occurrence of faults and other geological disturbances such as thinning of the seam, 'nip' or 'wash outs,' and so forth.

The National Coal Board.

The National Coal Board was constituted by the Minister of Fuel and Power (to whom it is responsible) in July 15, 1946, under the Coal Industry Nationalisation Act, 1946. Its duties were :—

(*a*) to work and get coal in Great Britain ;
(*b*) to secure the efficient development of the coal mining industry ;
(*c*) to supply coal without showing 'undue preference' to anyone, and to regulate qualities and sizes, quantities and prices so as best to further the public interest in all respects.

Its policy had also to promote health, safety and welfare of all employees, and to utilise their practical knowledge. Subject to certain directions from the Minister, the Board was solely responsible for managing the industry and running it on sound business lines.

The Board comprised a Chairman and a Deputy Chairman, and seven other members, some of whom were charged with responsibility for certain aspects of the Board's work ; *e.g.* production, labour, scientific, marketing, and finance. The N.C.B. officially assumed its duties on January 1, 1947, with headquarters in London.

For the new organisation the N.C.B. decided to group the pits into planning units of the size envisaged in the Reid Report. These units are known as Areas, and they now form the nucleus of management. There are 48 of them ; each is of a size not too large for effective supervision by their senior officials. In some cases they followed the group pattern created under private ownership, in others new grouping was required.

To avoid over centralisation the 48 areas are not directly responsible to headquarters. Instead 8 Divisions were formed, corresponding largely to the geographical distribution of the coal fields. In charge of each Division is a Board, collectively responsible to the N.C.B. The main function of these Boards is to frame a policy for their particular coalfield, to advise the N.C.B. on national policy, and to guide and help their own Area officials.

The names of the Divisions and their several component districts of the coalfields are as follows :—

Division.	*Districts.*
Scottish	East, West, Ayrshire.
Northern	Northumberland, North Durham, South Durham, Cumberland.
North Eastern	West Yorks, South East Yorks, South West Yorks.
North Western	North Lancs., mid-Lancs., North Wales.
East Midland	North Derby, Notts. and Lincs., Leicester with South Derby.
West Midlands	North Staffs., South Staffs.
South Western	West Wales, Cardiff, Newport, Gloucester with Somerset.
South Eastern	Kent.

Each Divisional Board resembles the N.C.B. in having a Chairman, Deputy Chairman, and other members (known as Directors), each in charge of a department of the Division's activities. The Chairmen were chosen from among men of wide administrative experience outside the industry; the other members had usually been in the industry previously. Each of these Boards has its own Divisional Headquarters.

The Divisional Boards carry heavy responsibility in the direction of the industry, but, having no legal entities, they function in the name of the N.C.B. In particular, the Divisional Finance Directors are specially responsible to the N.C.B. for sound finance.

The working of each Area is carried out in departments, corresponding approximately to those at N.C.B. Headquarters. The officials in charge of these departments constitute the Area Committee, which sits under the Chairmanship of an Area General Manager. He is responsible for Area management in all its aspects and answerable to the Divisional Board for its efficient working. His capacity for leadership is all-important to the success of the new organisation. But the

colliery manager remains statutorily responsible for the safe working of his pit, and its efficiency is still largely in his hands.

In most cases the Area Committee comprises about two dozen members, each covering one field of engineering, labour relations, marketing, coal preparation, estates, or accounts, etc. The Production Manager may deputise for the Area General Manager. In some Areas, usually those containing a large number of small collieries, control is by a small committee comprising a General Manager, Administrative Officer and Labour Officer.

Because of the urgent need for immediate improvement in output at the vesting date the first steps in reorganisation were short-term measures to that end. For example: concentration of men and equipment in the more productive seams and districts, and at the more productive pits; putting all available machinery to work, particularly conveyers; sending more men on to the coal face; recruiting and training more workers, including foreign workers.

In effect, during 1947 there was a nett increase of 26,000 in number of workers, making a tota of 711,400; the number of trunk conveyors increased by 1,500 or 16 per cent.; of 62 new locomotives delivered 32 were put to work underground. There was also an increase in the number of coal cutters and face conveyors, as well as in the more modern types of cutters and loaders.

Unfortunately these measures did not procure the desired output, largely because of the continued high rate of absenteeism and other labour troubles, and that in spite of the introduction of the five-day week on May 5, 1947. The output of deep-mined coal in 1947 was 187 m. tons, against a target of 190 m. tons. The Government's opencast workings produced an additional 10 m. tons.

The extension of working hours agreed to in November, 1947 (usually in the form of Saturday shifts) gave poor results, and the difficult labour situation early in 1948 led to the formation of a Joint Committee composed of representatives of the N.C.B. and N.U.M. which issued a Joint Report on Production in November 1948. The Report stated that the primary object, to produce maximum output of coal, depended largely on the number of men at the coal face, and recommended several measures to that end. In particular, to reduce the figure for absenteeism, which averaged about 14 per cent. in 1948, it was proposed that joint attendance committees of management and men be set up, with power to impose small fines and other disciplinary action, such as court proceedings or dismissal. But by a majority of 7 out of 10 the District Branches of the N.U.M. refused to accept these recommendations which representatives of their own National Executive had agreed, on account of the measures to stop absenteeism. Except in slump periods absenteeism has always been prevalent in coal mining in this country. But its ill-effect on production is vastly greater with mechanised methods than with hand getting. A proper understanding of the phenomenon is yet to seek, but a start has been made.*

The long-term policy of the Board in respect of mining operations proper is based largely on the recommendations of the Reid Report. It includes the development of 'horizon mining,' in which straight level roads are driven through the coal measures, of a kind suitable for locomotive haulage; the introduction wherever possible of 'room and pillar' systems, and of longwall retreating in preference to the more usual system of longwall advancing; the maximum use of coal-cutters and loaders and face conveyors; the extended use of electricity underground; the substitution of locomotive haulage (diesel and electric) for existing methods of rope-haulage and conveyors in roadways; and as a corollary, the introduction of mine cars of 1·5 tons to 3·5 tons capacity, in place of present tubs for cage winding; cars of capacity up to 6 tons are to be used with skip winding, which is to be extended where practicable; the Koepe system of winding is to receive further consideration. Large scale schemes for reorganisations of surface equipment and layouts are envisaged; plans for 37 major schemes and 21 of lesser size, and two new collieries and four new drift mines were either preparing or in course of execution during 1947.

To the greatest possible extent a variety of fully mechanised methods of cutting and loading are to be developed and applied, with due regard to their appropriateness to local conditions. The machines already established, and to be applied more widely and intensively, are mostly of British origin and designed for longwall work, *e.g.* the Meco-Moore cutter-loader; 30 of these machines are at work—mostly in the excellent conditions obtaining in the East Midlands Division.

RENTS AND ROYALTIES PAYABLE IN RESPECT OF MINERALS OTHER THAN COAL.

Common Surface Clay.—**The amount payable in royalty depends on the suitability of the clay for the purpose to which it is to be put and the rates are usually as follows :—**

Worked in the open, 3*d.* per ton but commonly fixed as so much per thousand bricks made and varies from 9*d.* to 2*s.* 6*d.* per thousand, according to the quality of the clay.

***Fireclay* as worked in collieries usually 2*d.* to 4*d.* per ton but special qualities command a higher royalty of from 8*d.* to 10*d.* per ton.**

***Ganister* frcm 5*d.* to 1*s.* per ton.**

*** 'Men in the Pits,' by Dr. F. Zweig. Gollancz. 1948.**

China clay and its derivatives, usually as follows :—

Blue and white China clay	3*s*. to 4*s*. 6*d*. per ton
Cream white	2*s*. „ 2*s*. 6*d*. „ „
Mica	9*d*. „ „
Pot granite	4*d*. „ „
Bricks	4*d*. „ „
Sand	4*d*. „ „

Oil Shale.—The dead rent merges into royalties and short workings are recoverable over the whole period of the lease. The royalty is 6*d*. to 1*s*. per ton, or when based on selling price, between $\frac{1}{18}$ and $\frac{1}{16}$ thereof.

Stratified Ironstone.—The certain rent varies from 8*s*. to £1 per acre. The royalty in Scotland from 6*d*. to 2*s*. 6*d*. per ton according to purity, or if on a sliding scale basis, from $\frac{1}{12}$ to $\frac{1}{4}$ of selling price. In South Walés about 8*d*. per ton, and in Cleveland about 5*d*. per ton.

Brown Hæmatite.—

Northampton	2½*d*. to 6*d*. per ton ; average 4*d*. per ton.
North Lincolnshire	9*d*. to 1*s*. 6*d*. ; average 1*s*. per ton (of 21 cwts.).
Leicestershire	6*d*. to 9*d*. ; average 7½*d*. per ton.
Oxfordshire	2*d*. to 3½*d*. per ton (of 21 cwts.).

Unstratified Ironstone.—Royalty is usually on a sliding scale basis, being a fraction of the selling price of the ore at or near the mine. These agreements vary slightly, but an example may be given of one which has been operative in the Furness district of Cumberland.

$\frac{1}{7}$th where the price of the ore is under 12*s*. per ton.
$\frac{1}{6}$th „ „ „ is between 12*s*. and 16*s*. per ton.
$\frac{1}{5}$th „ „ „ is above 16*s*. per ton.

Hæmatite.—In the case of hæmatite iron ore the certain rents vary from about £2 to £10 per acre.

BUILDING STONES.

Slate.—Royalty rent varies in amount in accordance with the character of the slate, etc., between $\frac{1}{20}$ and $\frac{1}{12}$ of the value of the slates at the quarry.

Other Stones.—Not possible to lay down hard and fast rules respecting rental value of all quarries. To quote two possible extremes, a *high class marble* near to good transport facilities would fetch a high rental, whereas a quarry of ordinary building *sandstone*, far distant from railway or canal, would probably be difficult to let, and then only at say 2*d*. per cubic foot. In the case of *Igneous Stone*, used for macadam, royalties ranging from 1*d*. to 4*d*. per ton are paid and for 'setts' from 3*d*. to 8*d*. per ton according to size. *Chalk* used with clay for making cement.—In a recent instance the royalty payable under the lease for the chalk and clay together was 6*d*. per ton of cement manufactured, and this was considered very favourable. *Sand and gravel* in the same instance were charged 2*d*. per cubic yard. These royalties were believed to be the lowest in the United Kingdom for these cement-making materials. The amount of the royalty charged in respect of *sand* and *gravel* is governed very largely by the position of the deposit and the demand, and ranged from 6*d*. to 1*s*. 6*d*. per cubic yard.

Gypsum.—The royalty varies from 6*d*. to 1*s*. per ton according to the quality of the mineral.

Salt.—The royalty for *rock* salt (Cheshire) amounts to about 2*d*. per ton. In the case of the sale from brine wells the royalty may be taken at 3*d*. per ton, to which should be added another 3*d*. per ton which the producer pays in tax for surface damage due to subsidence.

Fluorspar.—The rate varies from 1*s*. to 1*s*. 9*d*. per ton of dressed mineral sold.

METALLIFEROUS ORES.

Gold.—From $\frac{1}{15}$ to $\frac{1}{18}$ of the value of the gold raised.

Tin and Copper.—An average dead or certain rent is about 2*s*. to 7*s*. per acre. The royalty averages $\frac{1}{20}$ of the value of the ore at the mine.

Lead.—Variable and assessed on a sliding scale, the fraction varying with the selling price of the ore. The Great Laxey Mine in the Isle of Man, the ore of which contains silver, used to pay $\frac{1}{10}$ of the value of the ore ; other mines in the island $\frac{1}{12}$ to $\frac{1}{20}$.

Zinc.—The royalty in respect of zinc ore or blende is sometimes payable under a sliding scale, sometimes merely a fixed proportion of the dressed ore—usually about $\frac{1}{20}$th.

Barium.—The royalty on 'heavy spar,' as it is commonly termed, varies as from 9*d*. to 1*s*. 3*d*. per ton, but as high a figure a 2*s*. per ton has been charged. Usually, however, the royalty is from 3 to 5 per cent. of the selling price of the dressed spar at the mine.

Industrial legislation contained in the Mines and Quarries Acts, and the Orders, Rules and Regulations made under them, determine the conditions of extracting minerals. The whole body of legislation in recent years has been the subject of a comprehensive review by three Royal Commissions ; the first of these, appointed in 1906, was exclusively on coal mines and allied mines, and presented its reports in 1907 to 1910, and led to legislation in 1911. The second, on metalliferous mines and quarries, was appointed in 1910, reported in 1914, and has not yet been made the subject of legislative enactment. The third, appointed in December 1935, reported in December 1938, but, owing to the intervention of the war, its recommendations have not yet

been incorporated in an Act of Parliament. Certain portions of previous Acts were not repealed and will be found in the 1911 Act, and for the first time the spheres of demarcation between the Coal Mines Acts and the Factories and Workshops Acts were made clear. A large number of these Acts refer to the hours of work; thus in the 1908 Act deputies were allowed to work 9½ hours. The 1919 Act reduced the hours from 9½ to 8; the 1926 Act increased the hours by one hour longer; the 1930 Act reduced the hour again. The 1931 Act made deputies' hours 8½ hours, and the 1932 Act, which is in force at present (1945), has kept the deputies at 8½ hours. Boys may be employed according to the 1937 proposal only from 6 in the morning until 10 at night; this has not as yet been passed into legislation. The Government itself seems to accept the confusion by stating that the Coal Mines Acts may be cited as the Coal Mines Acts from 1887 to 1937, a space of some half century.

List of Principal Legislative Enactments in Force affecting Mines and Minerals.

1. An Act putting an end to life 'bondage' of miners, 1778.
2. The Land Tax Act, 1797 (sect. 4), and subsequent Acts.
3. Truck Acts, 1831, 1887, 1896.
4. Prohibition of Employment of Women and Girls in Mines; Regulation of Employment of Boys, and making other provisions relative to persons working in Mines, 1842.
5. Railway Clauses Consolidation Act, 1845 (sects. 77–85). See also *Howley Park Coal and Canal Company* v. *L. & N.W. Railway* (Law Reports, 1913).
6. Waterworks Clauses Act, 1847 (sects. 18–27). See also *New Moss Colliery* v. *Manchester Corporation* (Law Reports, 1908).
7. Acts for inspection of Coal Mines, 1850, 1855.
8. Crown Lands Act, 1866 (sects. 21–25).
9. Metalliferous Mines Regulations Acts, 1872, 1875.
10. Rating Act, 1874 (sects. 7–8).
11. Explosives Act, 1875 (sect. 59).
12. Slate Mines (Gunpowder) Act, 1882.
13. Public Health Act, 1875 (Support of Sewers) Amendment Act, 1883.
14. Coal Mines Regulation Acts, 1860, 1862, 1872, 1886, 1887–1908.
15. Quarries (Fencing) Act, 1887.
16. Quarries Act, 1894.
17. Mines (Prohibition of Child Labour Underground) Act, 1900.
18. Factory and Workshop Act, 1901.
19. Coal Mines (Weighing of Minerals) Act, 1905.
20. Notice of Accidents Act, 1906.
21. Mines Accidents (Rescue and Aid) Act, 1910.
22. Finance Acts: 1910 (sects. 20–27); 1912 (sect. 11); No. 2, 1915 (sect. 43); 1916 (sect. 46); 1917 (sect. 21); 1919 (sect. 33); 1920 (sect. 49).
23. Coal Mines Acts, 1911, 1914, 1919, 1930–1932, 1938, 1942, 1943.
24. Coal Mines (Minimum Wage) Act, 1912.
25. Coal Mines Regulation (Amendment) Act, 1917.
26. Education Act, 1918 (sect. 14).
27. Education (Scotland) Act, 1918 (sect. 17).
28. Petroleum (Production) Acts, 1918, 1934.
29. Income Tax Act, 1918 (First Schedule, Schedule A, No. III).
30. Coal Mines (Emergency) Acts, 1920, 1921.
31. Coal Mines (Emergency) Acts, 1920, 1921.
32. Mining Industry Acts, 1920–1926.
33. Employment of Women, Young Persons and Children Act, 1903, 1907, 1920 (sect. 1).
34. Mines (Working Facilities and Support) Acts, 1923, 1925. See Report of Mining Cases decided by Railway and Canal Commission Court under the Mines (Working Facilities and Support) Act, 1923, by P. J. Bamber.
35. Rating and Valuation Act, 1925.
36. Workmen's Compensation Acts, 1887, 1906, 1923–1934.
37. Rating and Valuation (Apportionment) Act, 1928.
38. Petroleum (Consolidation) Act, 1928.
39. Local Government Act, 1929 (sects. 2, 77 and Schedule I).
40. Coal Mines Act, 1940.
41. Mines (Working Facilities) Act, 1934.
42. Workmen's Compensation (Coal Mines) Act, 1934.
43. Public Health Act, 1936 (sects. 91, 93, 109).
44. Coal Act, 1942.
45. Coal Act, 1943.
46. Coal Industry Nationalisation Act, 1946.

NOTE.—Regulations made under the Coal Mines Act, 1911, are, with a few exceptions, published annually by the Stationery Office. See also Reports of Board of Trade under sect. 12 of Mining Industry Act, 1926 (Cmd. 3214, etc.) and under sect. 7 of the Coal Mines Act, 1930 (Cmd. 3905, etc.).

PRINCIPAL CLAUSES IN COLLIERY LEASE.*

Description of contracting parties (lessor and lessee) and of property demised.

Powers granted to lessee:—
- To break surface, make shafts, adits, etc.
- To win and work coal, bring to bank, make merchantable, dispose of.
- To work by instroke or outstroke or both.
- To make and dispose of coke and other products.
- To have necessary surface accommodation.
- *To have necessary wayleaves.
- To construct roads, tramways, railways, etc.
- To erect buildings, machinery, plant, etc.
- To work quarries of lime, clay, etc. (sometimes for own use only).
- To remove coals, dead and live stock, plant, etc., after expiration of lease.
- To relinquish at stated times before termination of lease.
- To renew lease for a further period.
- To generally do all things necessary for getting coal, etc.

Reservations to lessor:—
- Of mines and minerals not demised.
- *Of certain rights and wayleaves.
- Of use of ways, railways, etc.

'Habendum':—
- Lessee to have and hold property for a fixed term of years.

'Redendum':—
- Annual certain rent or deadrent, usually merging into royalty.
- Royalty per ton or otherwise.
- Rent for surface occupied.
- *Rent for wayleaves, waterleaves, or other facilities.

Provisoes:—
- No royalty payable in respect of colliery consumption.
- Power to make up short workings of previous years.
- Power to carry over excess workings to subsequent years.
- For distress in case of default in payments.
- For re-entry if rents, etc., remain unpaid for certain period.

Covenants on part of lessee:—
- For due payment of rents and royalties.
- For due payment of taxes.
- For compensating for damage done to surface or to neighbours.
- For erecting (or against erecting) buildings, houses, coke-ovens, etc.
- For keeping proper accounts accessible to lessor, and rendering the same.
- For keeping proper mine plans, and permitting inspection of mine.
- For leaving proper barriers.
- For working in approved and miner-like manner.
- Against sub-letting without authority.
- For giving up possession in good condition at determination of lease.
- For keeping mine, plant, buildings, etc., in good repair.
- For properly fencing or securing shafts, adit mouths, etc.
- For giving lessor power to purchase plant, etc., at a valuation on determination of lease.

Covenants on part of lessor:—
- For proper title.
- For quiet enjoyment.

Arbitration clause.

Leases of ironstone mines as also of metalliferous mines follow practically the same lines; as regards the latter, it is usually set forth that the royalty shall be a certain part of the value of the minerals, cleaned, dressed, calcined, or otherwise rendered merchantable, as the case may demand, at the expense of the lessee. There are often clauses specifying that a certain amount of development work, driving, sinking, etc., shall be performed.

A tacknote or license to prospect is often granted; this differs from a lease, inasmuch as it transfers no interest in the property. Its usual form is a license for one year to explore for all or for certain specified minerals within a definite area, usually for a nominal consideration, the licensee making compensation for all damages, and paying a royalty on all minerals gotten and sold. The license is generally renewable at the option of the licensee for a term of years, usually three, and the licensee is entitled to a lease upon conditions specified; this specification often takes the form of a schedule embodying the conditions of a draft lease.

*** This has reference to the principal clauses contained in colliery leases prior to the acquisition of the coal and adjacent minerals by the State. It is presumed that the Coal Commission will in granting new and consolidated leases retain many of these clauses but not so in respect of those relating to way-leaves.**

Classification of Mineral Deposits.

A mineral deposit may be defined as a portion of the earth's crust containing mineral matter of intrinsic value under favourable conditions.

The mineral substances that form the subject of mining operations may be classified as under :—

Group I., Fuels ; II., Ores ; III., Salts ; IV., Gems ; V., Rocks.

Group I., contains the different varieties of coal, asphalts, bitumen, and other solid hydrocarbons, mineral oils, etc., while sulphur may conveniently be included.

Group II. contains the various heavy metals either in the native state or in combination.

Group III. contains the haloids, sulphates, carbonates, silicates, phosphates, borates, etc., of the alkaline earths and alkalies.

Group IV. contains those minerals that are prized as gems on account of their hardness, brilliancy and transparency, as well as the semi-gems, such as opal, turquoise, etc., which though opaque are prized as precious stones on account of the beauty of their colouring and their rarity.

Group V. comprises the various rock masses, such as granite, slate, limestone, etc., the exploitation of which is more properly considered under quarrying.

With respect to their mode of occurrence, mineral deposits may be classified morphologically as follows :—

Tabular = Beds, veins.
Irregular = Masses, lenses, pipes, etc.

A more complete classification, based on genetic as well as morphological characters, is as follows :—

Class I.—Symphytic; **Syngenetic, contemporaneous or stratified**		**Group *a*, clastic.** **„ *b*, formed by chemical agencies.** **„ *c*, formed by organic agencies.** **„ *d*, disseminated through beds.**
Class II.—Epactic; **Epigenetic, subsequent or non-stratified.**	**Sub-Class A— Veins.**	**Group *a*, fissure** **„ *b*, bedded.** **„ *c*, contact.** **„ *d*, gash.**
	Sub-Class B— Masses.	**Group *a*, stockworks.** **„ *b*, disseminated in igneous rocks.** **„ *c*, connected with igneous rocks.** **„ *d*, connected with soluble rocks.**

Class I.—Group *a* includes auriferous alluvials, tin-bearing alluvials, ironsands, etc. Group *b* contains deposits due to chemical precipitation, to evaporation or to metasomatic changes. Practically all the stratified ironstones belong to this group. Of group *c* the most important representative is coal. Group *d* includes the Knottensandstein of Mechernich, the Kupferschiefer of Mansfeld, the Banket beds of Johannesburg, and similar deposits.

Class II.—Sub-Class A. Group *a* includes most of the important vein systems of the world, such as those of Cornwall, etc.

Group *b* includes veins parallel to the stratification.

Group *c* embraces certain veins following the contact of dissimilar rocks. (Not important.)

Group *d* contains veins carrying galena and zinc blende that characterise certain limestone districts, e.g., that of Missouri. (Sometimes classed in sub-class B.)

Sub-Class B. Group *a* consists of masses traversed by minute veinlets carrying ore, such as the tin deposits of Saxony.

Group *b* comprises such deposits as the Kimberley diamond-bearing pipes, the copper deposits of Lake Superior, etc.

Group *c* are very largely lenticular in form ; the pyrite deposits of the Huelva district are a typical example.

Group *d* may be represented by the red hæmatite deposits of Cumberland and Lancashire.

Branches of Mining.

I. Prospecting, the most important part of which is 'boring.'

II. Exploiting, including the various operations of opening up mineral deposits by shafts or adits, extracting and transporting the mineral, securing, pumping and ventilating the workings, and the proper care of the men employed.

III. Dressing or preparing the mineral extracted for the market.

COAL.*

CLASSIFICATION.

Various classifications of coal have been attempted from time to time. Perhaps the best is that adopted by the World Geological Congress, which met at Toronto in 1913, which took as the basis of their classification the fuel ratio

$$\frac{\textbf{Fixed carbon}}{\textbf{Volatile matter}}$$

*** See article 'Coal' by R. A. S. Redmayne in the 13th Edition of the *Encyclopaedia Britannica*.**

and in the case of sub-bituminous coals (inclusive of brown coal and lignite) the split volatile ratio

$$\frac{\text{Fixed carbon} + \text{Volatile combustibles}}{\text{Hygroscopic moisture} + \frac{1}{2}\text{ Volatile combustible}}$$

Coal being divided into four main classes and three sub-classes, letters instead of names being used, namely A, B, C and D. A corresponding to anthracite, B to bituminous coal, C to cannel and D to sub-bituminous coal. Between anthracite and bituminous coals occur the *semi-anthracites* or dry steam coals of South Wales and elsewhere, and the smokeless steam coal; whilst in the sub-bituminous class occur such different coals as black lignite, little distinguishable in appearance from ordinary bituminous coal, and brown coal.

Commercially speaking bituminous coal is divisible into gas, coking, house, manufacturing and steam coal.

The following are some characteristics and analyses of various coals:—

Professor Elwood A. Moore, the American authority, gives the following as an average composition of *brown coal* compiled from analyses of these coals from all parts of the world:

Moisture	14·42 per cent.
Volatile matter	40·78 „ „
Fixed carbon	36·00 „ „
Ash	9·32 „ „
Sulphur	1·14 „ „

Lignite differs from *brown coal* in that it has retained its woody structure.

The calorific value of brown coal and lignites varies greatly, *e.g.* 3·270 to 5·760 B.T.U. (brown coals of Germany), 8,000 to 9,600 B.T.U. (Canadian lignites).

Bituminous coal comprises many sub-classes, *e.g.* (1) *gas coals* or those bituminous coals which have the highest volatile hydrocarbon content, the most remarkable of which is 'Cannel' coal. Some cannels are very rich in volatile matter, that at Newbattle yielding 13,720 cubic ft. of gas (of 35 candle power) per ton of coal. It is a requirement of a good gas coal that it should yield about 10,500 cub. ft. of gas per ton with an illuminating power of 16 candle power.

(2) *Coking Coals.*—Coals which are possessed of the quality of intumescence or swelling upon the application of heat. A high class coking coal would have some such analyses as the following (*e.g.* of a well-known Durham Colliery):—

Fixed carbon	67·31 per cent.
Volatile hydrocarbon	25·61 „ „
Sulphur	0·78 „ „
Ash	5·10 „ „
Moisture	1·20 „ „
Phosphorus	0·005 „ „

The purest *coke* in the world is Ramsay's Garesfield (Durham) with

Carbon	97·6 „ „
Sulphur	0·85 „ „
Ash	1·55 „ „

Anthracite, which has a high fixed carbon content, and a low oxygen content, and *lignites* and *brown* coals, which have a low fixed carbon content and a high oxygen content, do not coke.

The sub-bituminous coal of Waikato, New Zealand, which is a glossy black immature coal, has a calorific value of 11,000 B.Th.U.

(3) Nearly all coals can be applied to domestic heating. It is largely a question of convenience and price as to what class of coal is employed as a *house coal.*

(4) *Gas coals* are usually coals which give off at least 10,000 cub. ft. of gas per ton of coal. A characteristic analysis of a good Durham gas coal shows a content.

Fixed carbon	62·32 per cent.
Volatile hydrocarbons	31·32 „ „
Sulphur	0·41 „ „
Ash	4·35 „ „
Moisture	1·60 „ „

Yield of gas 10,800 cub. ft. per ton with an illuminating power of 18·10 candles.

Cannel Coal contains the highest volatile hydrocarbon content of any coal. The following analysis is that of a Scotch cannel.

Fixed carbon	42·48 per cent.
Volatile hydrocarbons	52·88 „ „
Sulphur	0·22 „ „
Ash	3·10 „ „
Moisture	1·32 „ „

This coal gives 14,135 cub. ft. of gas per ton with an illuminating power of 37·36 candle power.

(5) *A manufacturing or iron smelting coal*, though raw coal is seldom used in these days for the smelting of iron, should be low in phosphorus, sulphur and ash content and possess a high fixed carbon content. The phosphorus and sulphur are detrimental to iron, and the ash not only goes to form slag, but detracts from the heating power of the coal. In (6) *steam coal*, the items of chief importance are the heating power, the character of the ash, and the sulphur content. The coal should have a sufficiency of hydrocarbons to permit of easy ignition and consumption of the fixed carbon ; beyond this it conduces to the formation of smoke. Incombustible matter reduces the value, so the ash content should be low and of a non-fusible character, as fusible ash forms clinker which is injurious to the firebars, necessitates considerable stoking and loss of heat. The following may be given as the composition of a first-class smokeless steam coal from the Rhondda Valley :—

Moisture	1·24
Volatile hydrocarbons	18·53
Fixed carbon	77·19
Ash	3·04

Heating value, 7,755 calories.
Evaporation power, 14·44.

(7) *Anthracite* is coal from which nearly all the volatile hydrocarbons have been expelled. (Some steam coals, as, for instance, the *dry steam coals* of South Wales, in the matter of fixed carbon content, stand between the ordinary steam coals and anthracite.)

Anthracite is hard, compact, glossy and difficult to ignite. Its calorific value is very high, attaining to a maximum of 15,531 B.Th.U. (8,624 calories) in the case of the best Welsh anthracite and an evaporative power of 16·06 lbs. of water. The composition of a good anthracite (Stanllyd Vein Blaina Colliery, Carmarthenshire) shows :—

Fixed carbon	93·76 per cent.
Volatile matter	5·09 „ „
Ash	1·15 „ „
Sulphur	0·75 „ „

and an inappreciable percentage of moisture.

Constitution of Coal.

The four constituents of coal, as identified by Dr. Marie Stopes, are :—

(1) Fusain. (2) Durain. (3) Clarain. (4) Vitrain.

Some authorities (*e.g.* Stach, *Glückauf*, 1927, p. 759, Kellett, *Trans. Inst. Min. Eng.*, vol. lxxv., 1928, p. 400) hold that Clarain is merely a mixture of Vitrain and Durain. In the U.S.A. these three classes are generally spoken of as Anthraxylon, Attritus, and Fusain. Fusain forms, usually, under 10 per cent. of a coal seam and is the highest in ash, this ash being always high in lime ; it also usually carries more salt than the rest of the seam. Vitrain is very low in ash, generally under 0·5 per cent. Durain ash contains mainly silica and alumina. Fusain is non-coking, but its calorific power is high and it is valuable for dust-firing. It is now generally admitted that Clarain is not a true constituent. (See papers by Prof. G. A. Hickling in *Trans. Inst. Min. Eng.* and *Proc. S. Wales Inst. Eng.*)

Calorific Power.

The calorific power may be calculated from the ultimate analysis by the 'Deutscher Verband' formula :—

$$\text{Cal. power in calories} = 81\,C + 290\left(H - \frac{O + N}{8}\right) + 25\,S - 6\,W,$$

where C, H, O, N, S, and W are the percentages, respectively, of Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, and Moisture.

Gontal's formula is applied where only the proximate analysis (percentages of fixed carbon, volatile matter and ash) is known :

Let C be percentage of fixed carbon, V of volatile matter, A of ash ; then

$$\text{Cal. power in calories} = 82\,C + a\,V,$$

where a is a coefficient depending upon the percentage of volatile matter in the ash-free coal, *i.e.* upon $\frac{100\ V}{100 - A}$ as follows :—

$\frac{100\ V}{100-A}$	5	10	15	20	25	30	35	40
a	145	130	117	109	103	98	94	80

The ash of coal varies usually between 2 and 15 per cent.

1 lb. of ordinary coal requires theoretically 130 cub. ft. of air for complete combustion.

COKE.

Ordinary bituminous coal, containing 25 to 30 per cent. of volatile matter, coked in a modern regenerative bye-product coke-oven plant, yields approximately :—

Coke . . .	70–75 per cent.	Ammonia as ammonic sulphate	1–1·25 per cent.
Tar . . .	3·5–4·5 „	Crude benzol	1 „

Surplus gas, 3,000 to 5,000 cub. ft. per ton of coal. Total gas, 9,000 to 10,000 cub. ft. per ton of coal.

The composition of this gas is about as follows :—Hydrogen, 48 to 65 per cent.; methane, 25 to 34 ; carbonic oxide, 6 to 8 ; carbonic acid, 2 to 2·5 ; hydro-carbons, 2 to 4 ; nitrogen, etc., 5 to 12 per cent. The calorific power is about 480 to 600 B.Th.U. gross, or 425 to 550 B.Th.U. net per cub. ft.

Modern bye-product ovens connected with ironworks are often fired with blast-furnace gas, so that the whole of the coke-oven gas is rendered available. Blast-furnace gas contains about : carbonic oxide, 30 per cent.; carbonic acid, 10 per cent. ; hydrogen, 1 per cent. ; nitrogen, etc., 59 per cent.; its net calorific value is about 100 B.Th.U. per cub. ft. See 'Notes on the Utilisation of Blast-furnace Gas,' by W. B. Baxter, *Journ. Iron and Steel Inst.*, vol. cxxviii, p. 71.

WEIGHT OF COAL.

The specific gravity of coal varies from 1·1 to 1·6, most bituminous coals approximating to 1·3. The following table shows the weight of coal contained in one acre of superficial area per inch thickness of seam, etc.

TABLE OF THE WEIGHT OF COAL IN DIFFERENT CIRCUMSTANCES.

Specific Gravity.	Weight in the Natural Bed, per Acre, per Inch Thick, in Tons.	Weight of a Cubic Foot in the Broken State, in Lbs.	
		Large Coal.	Small Coal.
1·10	111·411	42·62	37·12
1·15	116·475	44·56	38·81
1·20	121·540	46·50	40·50
1·25	126·604	48·43	42·18
1·30	131·668	50·37	43·87
1·35	136·732	52·31	45·56
1·40	141·796	54·25	47·25
1·45	146·860	56·18	48·93
1·50	151·925	58·12	50·62

Specific gravity × 101·283 = weight in tons per inch thick per acre.

To find the contents of coal of any given specific gravity per acre multiply the figure in the table by the thickness of the seam in inches; the thickness measured along a vertical line should always be taken, as the correct result will thus be obtained, whatever may be the inclinatior of the coal seam.

The weight of coal in its broken state, that is, as it comes to the surface, in tubs or otherwise, will depend on its largeness; the large has been computed to weigh in proportion to the solid coal as 62 to 100, and the small as 54 to 100.

The calculation now most commonly adopted in the North of England to ascertain the weight of coal in the solid state is to reckon 19 cwts. per cubic yard = 78·815 lbs. per cubic foot. On this calculation, a seam 1 foot in thickness would contain 1,532 tons 13 cwts. 1 qr. 10 lbs. per acre, and a seam 1 yard thick would contain 4,598 tons per acre.

A summary way of reckoning the quantity of available coal in a given area of a seam is to take an acre of coal 1 inch thick to produce 100 tons. This leaves a sufficient margin for faults and losses in barriers and in working.

SIZING OF COAL.

In the coal trade coal is often sold by size, but there is no uniformity in practice even in the same field. Above 4 ins. to 6 ins. it is usually sold as Best Coal, House, or Best House ; a very general scheme of designations is :—

Cobbles . . .	between 5 ins. to 6 ins.	and about 3½ ins. to 3 ins.
Treble nuts . .	„ 3½ „ 3 „	„ 1½ „
Double nuts . .	„ 1½ ins.	„ 1 in. to ¾ in.
Single nuts . .	„ 1 in. to ¾ in.	„ ½ in.

Duff, slack or gum below ½ in.

Some collieries also make beans, say about $\frac{5}{8}$ in. to $\frac{3}{8}$ in. and peas, say about $\frac{3}{8}$ in. to $\frac{3}{16}$ in. The dimensions may signify plate screens with round or with square holes, bar screens or wire gauze; in the two latter they may be measured in the clear or centre to centre. All these different methods are in use.

With reasonably closely sized coal of whatever dimensions it is found that as ordinarily heaped the coal occupies 55 per cent. of the total volume of the heap.

The proper sampling of coal is a difficult problem that is now attracting much attention. The methods of the British Standards Institution are generally used.

METALLIFEROUS MINERALS.

In America they make a further class with what they call Industrial Minerals. (See correspondence in 1936 between Professor H. Louis and the American Institute of Mining and Metallurgical Engineers.)

By *metalliferous* minerals or *metallic* minerals are meant those minerals that are technically utilisable for the extraction of the ordinary commercial heavy metals, metals of the alkalies and alkaline earths being excluded; this is almost identical with the meaning of *ores*, or with Group II, of above classification. In United States of America and Canadian statistics, a wider meaning is given to *non-metallic* minerals, which includes all minerals not actually used for the extraction of metals, *e.g.* ochre, although this is an oxide of iron, because it is used as a pigment and not as a source of iron.

Composition of more important Ores.

Name.	Formula.	Percentage of Metal.
Magnetite	Fe_3O_4	Fe 72·4
Hæmatite	Fe_2O_3	,, 70
Limonite	Fe_2O_3,H_2O	,, 60
Brown hæmatite	Hydrated ferric oxide, with 10–15 per cent. H_2O	,, 45–55
Siderite	$FeCO_3$	,, 48·3
Ilmenite	$(TiFe)_2O_3$	,, 30–40
Pyrites	FeS_2	,, 46·7
Pyrrhotite	Fe_7S_8	,, 60·5
Pyrolusite	MnO_2	Mn 63·3
Manganite	$Mn_2O_3H_2O$	,, 62·5
Wad	Impure hydrated manganese oxide	,, 25–50
Chalcopyrite	$Cu_2SFe_2S_3$	Cu 34·6
Chalcocite	Cu_2S	,, 79·8
Malachite	$2(CuO)CO_2H_2O$	,, 56
Cinnabar	HgS	Hg 86·2
Galena	PbS	Pb 86·6
Cerussite	$PbCO_3$	,, 77·5
Anglesite	$PbSO_4$	,, 68·3
Blende	ZnS	Zn 67
Calamine	$ZnCO_3$	,, 52
Stibnite	Sb_2S_3	Sb 71·8
Mispickel	$FeAs_2S_2$	As 46
Cassiterite	SnO_2	Sn 78·7
Wolfram	$(FeMn)OWO_3$	W 70
Scheelite	$CaOWO_3$	,, 74·8

Ironstone.

Ironstone is the term applied to stratified or symphytic deposits workable for iron, iron ore to epactic deposits, veins or masses. Bessemer ore or hæmatite ore is generally understood to mean iron ore with less than 0·035 per cent. of phosphorus when the ore contains about 50 per cent. of iron. Such ores are usually quoted on a basis of 50 per cent. of iron, with a definite increase or deduction in price for each unit of iron above or below that figure, and a penalty for every unit of silica above a given percentage, often 8 per cent.

The yield of ironstone is often taken roughly at 2,000 tons per foot thick per acre.

TABLE OF BRITISH MESOZOIC IRONSTONES.

Formations.			*Name of Ironstone.*
CRETACEOUS—Neocomian		Lower Greensand	Seend, Wiltshire.
	Wealden	Weald Clay	
		Hastings Sand .	Sussex and Kent. Westbury, Wiltshire, Claxby, Lincolnshire.
JURASSIC	Upper Oolite		
	Middle Oolite . . .	Corallian . . . Oxford Clay	Dover, Kent. Westbury, Wiltshire.
	Lower Oolite . .	Great Oolite Estuarine Beds Northampton Sands	Northamptonshire. Cleveland Dogger or Top Seam.
	Upper Lias	Upper Lias Clay Toarcian . . .	Isle of Raasay.
	Middle Lias . . .	Middle Lias Limestone . .	Cleveland Main Seam. Cleveland Pecten Seam. Cleveland Avicula Seam.
		Marlstone. . .	Blenheim, Oxfordshire. Melton Mowbray, Leicestershire. Caythorpe, Lincolnshire.
	Lower Lias		Frodingham, Lincolnshire.

COMPOSITION OF BRITISH MESOZOIC IRONSTONES, DRIED AT 100° C.

	Iron.	Silica.	Lime.	Sulphur.	Phosphorus.	Loss on Ignition.
	per cent.	per cent.	per cent.	per cent.	per cent.	per cent.

Oxfordshire	28	13	11	0·15	0·3	35
Raasay	25	10	17	0·5	1·0	20

HAEMATITES.

These weigh 3–3·5 tons per cubic metre in place, 2½ tons per cubic metre in mine cars, 2 tons per cubic metre stacked.

COPPER, TIN, LEAD AND ZINC ORES.

Copper, tin, lead and zinc ores are usually sold by assay. The value is calculated on the current market price of the metal multiplied by the percentage of metal present less the percentage estimated to be lost in the operation of smelting; from the value thus found there is then deducted the 'returning charge,' being the estimated cost of smelting the ore, including the smelter's profit, etc. The following were the generally accepted (pre-war) methods :—

COPPER ORES.—Weight paid for is gross weight less moisture and less 1 per cent. draftage. Wet assay less 1 per cent. for ores assaying 3–4 per cent. (deduction varied proportionately for richer or poorer ores); for value per unit (1 per cent.) take 0·01 of price of best selected copper, less returning charge of 2*s*. 3*d*. to 2*s*. 6*d*.

Example.—Cargo of 1,000 tons ore assaying 4 per cent. copper, 1¼ per cent. moisture. Net weight $= 1{,}000 - \left(\frac{1{\cdot}25}{100} \times 1{,}000\right) = 987{\cdot}5$ tons.

4 per cent. − 1 per cent. = 3 per cent. copper to be paid for.
Best selected quoted that day 82*l*. 10*s*. per ton = 16*s*. 6*d*. per unit, less 2*s*. 3*d*. returning charge = 14*s*. 3*d* 3 units at 14*s*. 3*d*. = 42*s*. 9*d*. per ton of ore.
Value of cargo 987·5 tons at 42*s*. 9*d*. = 2,110*l*. 15*s*. 7½*d*.

LEAD ORE.—Weight paid for is net dry weight. Percentage paid for is dry assay less 4 units, on basis of soft foreign lead price in London, subtracting 40*s*. per ton for returning charge. Silver above 3 oz. per ton paid for at current rate for fine silver. Price is understood to be delivered smelter's works.

Example.—150 tons net of galena assaying 78 per cent. of lead and 5 oz. of silver per ton quotations being: lead, 20*l*. per ton; fine silver, 2*s*. 3*d*. per oz. Lead, 150 tons at (78 − 4) per

cent. = 111 tons at 20*l*. = 2,220*l*., less 150 tons at 40*s*. = 1,920*l*. Silver, 150 × (5 − 3) oz. = 300 oz. at 2*s*. 3*d*. = 33*l*. 15*s*. Total value of ore, 1,953*l*. 15*s*. Silver quotations are generally in pence per ounce standard, *i.e.* 925 per mil fine.

Zinc Ore.—Weight paid for is net dry weight. From percentage of zinc, as determined by wet assay, subtract 9 units, multiply by $\frac{18}{20}$ of price of spelter, and subtract returning charge of 3*l*.; difference is price per ton delivered smelter's works.

Example.—If ore assays 50 per cent., London quotation for spelter being 18*l*., the ore is worth £ $\left(\left[\frac{50-9}{100}\cdot\frac{18}{20}\cdot 18\right]-3\right)$ = 4*l*. 0*s*. 3*d*. per ton.

The general gangue of most ores is quartz; solid quartz averages about 165 lbs. per cub. ft. (13½ cub. ft. to the ton), broken about 100 lbs. (22½ cub. ft. to the ton), but varies considerably; the weight of veinstuff containing metalliferous minerals can be calculated from the specific gravity of the minerals.

Table of Specific Gravities and Weights per Cubic Foot of Minerals.

Mineral.	Sp. gr.	Cwts. per cub. ft.	Mineral.	Sp. gr.	Cwts. per cub. ft.
Copper pyrites	4·1–4·3	2·34	Hæmatite	4·5–5·3	2·73
Copper glance	5·5–5·8	3·15	Brown hæmatite	3·4–4·4	2·17
Malachite	3·7–4·0	2·20	Spathic ore	3·4–3·9	2·04
Cinnabar	8·9–9·0	5·00	Pyrolusite	4·8–4·9	2·67
Galena	7·3–7·7	4·18	Cassiterite	6·4–7·1	3·76
Cerussite	6·4–6·5	3·60	Wolfram	7·1–7·6	4·12
Anglesite	6·1–6·4	3·50	Scheelite	5·9–6·1	3·34
Zinc blende	3·9–4·2	2·23	Quartz	2·5–2·8	1·50
Calamine	4·0–4·5	2·40	Calcspar	2·5–2·8	1·50
Stibnite	4·5–4·6	2·50	Dolomite	2·8–2·9	1·56
Pyrites	4·8–5·2	2·78	Fluorspar	3·0–3·2	1·73
Mispickel	6·0–6·4	3·45	Felspar	2·5–2·8	1·50
Magnetite	4·9–5·2	2·80	Barytes	4·3–4·7	2·51
Ilmenite	4·5–5·0	2·64	Witherite	4·3–4·4	2·41

A rib of mineral 1 in. thick = 3 cub. ft. per square fathom.

Calculation of Mineral Mixtures.

The percentages of two minerals present in a mixture can easily be calculated if the sp. gr. of the mixture and of the ingredients is known. A convenient method is that proposed by R. T. Hancock.

Take a weight of x grms. of the mixture containing two ingredients of sp. gr., a and b respectively, where $\frac{1}{x} = \frac{1}{a} - \frac{1}{b}$ or $x = \frac{ab}{b-a}$; then the volume of this weight of a alone will differ from that of the same weight of b alone by 1 c.c., and for every 1 per cent. of a (the lighter substance) present in the mixture, the volume will be greater by 0·01 c.c. than the volume of b alone and for every 1 per cent. of b present, less by 0·01 c.c. than the volume of b alone. It is usually convenient to take $10x$ grms., when the differences will be 0·1 c.c.

Example.—To determine percentage of cassiterite (sp. gr. 7) and 'black sand' (sp. gr. 4·5) in a mixture of these. Since $\frac{1}{4{\cdot}5} - \frac{1}{7} = \frac{1}{12{\cdot}6}$, take 126 grms. Volume of mixture, measured by pouring the mixture into a burette partly filled with water and noting the difference in the burette readings, = 20 c.c. Volume of 126 grms. of black sand would be $\frac{126}{4{\cdot}5}$ = 28 c.c. Hence percentage of cassiterite = 10 (28 − 20) = 80 per cent.

Non-metallic Minerals.

Non-metallic minerals in this country are generally held to include Groups III. and IV. (p. 854), *i.e.* compounds of the alkaline earths and alkalies and gems, together with such minerals as quartz, coal, sulphur; a mineral such as scheelite may be classed either as a metallic mineral or as a salt; in such a case the object for which the mineral is worked is generally taken into account, *e.g.* scheelite would usually be classed as a metalliferous mineral because it would be worked as a source of tungsten and not as a source of lime.

BORING.

Boreholes are put down by one or other of the following methods :—

I. Percussive. (a) Using solid rigid rods.	II. Rotary : A. Core drills.
(b) Using ropes.	(a) Using diamond.
(c) Using hollow rods (water-flush method).	(b) Using steel cutting teeth.
	(c) Using chilled shot.
(d) Using a hydraulic ram.	B. Hydraulic rotary oil drill.

Generally speaking, percussive methods are used when the primary object is to get a hole down rapidly, where information as to the nature of the ground passed through is of less importance, whilst rotary core drills, by the use of which a more or less continuous core is obtained, are employed when an accurate knowledge of the strata passed through is the first consideration. Sometimes both methods are combined ; thus in some of the boreholes put down in Kent, boring through the secondary rocks was performed by percussion, whilst rotary core-boring was substituted after the coal measures had been reached. Percussion boring by the ordinary 'English' method can be used to depths of about 500 ft., costing about 10*s*. to 20*s*. per foot, and advancing 2 ft. to 6 ft. per twenty-four hours. Beyond this depth a free-falling cutter must be used, and in this way depths of 3,000 ft. or more may be reached.

Rope boring with round ropes on the American system is used almost exclusively in boring for oil, salt, etc. The plant for a hole 2,000 ft. deep would weigh about 80 tons complete and cost about 2,000*l*.; holes range from 6 ins. to 15 ins. in diameter. In Pennsylvania and Ohio such boring has been done for as little as 2*s*. per foot, and contracts are usually let at prices ranging from 4*s*. to 8*s*. The rate of boring is from 20 ft. per day upwards. In Middlesbrough, 8-in. holes have been put down to depths of about 1,000 ft. at a cost of about 8*s*. per foot with a speed of 60 ft. per day. Boring with flat ropes by the Mather and Platt system is used for very large boreholes, as for instance for waterworks ; holes up to 45 ins. in diameter have been bored by this method.

The water-flush method, of which there are many varieties (Fauck, Raky, etc.), is used in hard rocks for boreholes of medium size (rarely under 8 ins. in diameter). Very fast boring can be done in this way ; e.g. in the Ruhr district a borehole was put down to a depth of nearly 2,000 ft. at an average speed of 157 ft. per twenty-four hours ; 30 to 50 ft. is quite a usual rate down to depths of about 2,000 ft., and over 20 ft. a day has been bored down to a depth of over 3,000 ft. (See 'North Wales Coalfield, Exploration by Rapid Boring,' by R. Foster. *Trans. Inst. M.E.*, vol. cvii, 1918.)

The hydraulic ram method appears to offer certain important advantages, especially for boreholes of moderately large diameter, but has hardly passed the experimental stage. The best known example of this method of boring is the Wolski and Frich boring apparatus.

Core Boring.

Diamond boring is in use to-day for hard rocks ; the main drawback is the high price of the 'diamonds' (bort, used in the softer rocks, costs 2*l*. to 3*l*.* per carat, carbon costs 6*l*. to 12*l*. per carat), which tells severely against boreholes larger than 6 ins. in diameter. The cost of diamond boring in this country is about 7*s*. 6*d*. per foot down to 500 ft. and 12*s*. to 18*s*. down to 1,500 ft. for a 5-in. borehole. A 5-in. borehole put down in Scotland to 1,800 ft. cost only 6s. 4d. per foot ; the rate of advance was about 6 ft. per day. In British Columbia a borehole 2,200 ft. deep cost 8*s*. 6*d*. per foot, and was bored at the rate of 10 ft. per day. In Victoria the Government does much boring to aid prospectors ; the bores are mostly shallow, but in one case a depth of 1,110 ft. was reached in about 120 days ; the average cost of boring in coal measures in 1912 was 9*s*. 3*d*. and in the harder rocks 14*s*. per foot. In Nova Scotia 2 in. diamond boreholes put down by the Government in moderately hard ground to depths of 200 to 400 ft. averaged about 9*s*. per foot in 1913.

Steel cutting teeth can only be used in tolerably soft ground. The cutter should make 15–25 r.p.m. A 10-in. borehole in Kent was put down by this method by the Calyx Company to a depth of 1,400 ft., the speed at times reaching 10 ft. per hour.

The chilled shot method is very generally applicable, and is used for relatively large bore holes in hard ground. The cutter should run at 100–150 r.p.m. ; about No. 5 shot is generally used. It is usually somewhat slower but cheaper than diamond boring. The consumption of shot with a cutter 4½ ins. in diameter ranges from 0·15 lb. per foot bored in shale to 1·2 lbs. in hard sandstone, but may be much higher in broken ground, where shot escapes into the fissures. In Nova Scotia 6 in. Government boreholes by this method averaged 10*s*. 6*d*. per foot in 1913.

* Under conditions at present existing, e.g. high wages and high cost of materials, the figures quoted under this heading would have to be materially increased in order to be severally applicable for 1949.

The hydraulic rotary drill is the name given to a form now much used in boring oil-wells; it cuts out the whole of the material, leaving no core, the debris being brought to the surface by a water-flush. Over 100 ft. per day has been bored by this method.

Boreholes, especially those bored by rotary methods, are apt to deviate from the vertical, and a number of ingenious appliances have been devised for determining the amount and direction of the deviation. This is specially important when boreholes are put down in connection with the freezing method of shaft sinking (see p. 869, also *Trans. Inst. Min. Eng.* 1929-30, vol. lxxix, p. 309). See also for methods adopted for the determination of the amount of deviation from verticality and deflection of boreholes Vol. 1 'Modern Practice in Mining,' by Sir R. A. S. Redmayne, third edition, Longmans Green & Co., where a good example of the survey of the east borehole sunk by Turf Mines, Ltd., Transvaal, is given.

Location of Bore-holes for Valuation of Alluvial.*

When ground is systematically tested by pits or boreholes at regular intervals, three conventional views are possible:—

1. That there should be so many pits or holes per acre, or
2. That the distance between pits or holes should be so much, or
3. That no point on the ground should lie beyond a certain distance from a pit or hole.

The first two are those most generally held, but the last seems the most logical, and to attain it with the least amount of work the holes should lie at the corners of a series of equilateral triangles, the length of whose sides, or the distance of the pits apart, is equal to the maximum distance under condition (3) multiplied by $\sqrt{3}$. A line is run in any desired direction and staked at intervals equal to the distance between pits. From these stakes lines are turned off at angles of 60° or 120°, and staked at similar intervals starting from the turning-off point. The stakes are numbered to indicate their position on their own line and the number of the turning-off point, so that the pits sunk at them can be readily identified.

The advantages of this method over the more usual square lay-out are considerable. There is 6 per cent. less work involved in the lay-out of the holes, and 23 per cent. less in the sinking and sampling. The computation of values can also be more accurately done. Interpolation of values can be done on the plan, much as in contouring from spot levels, and a reliable assay plan prepared. (*R. T. Hancock.*)

Geophysics for the Location of Minerals.†

Magnetic methods; electric methods (self-potential method, equi-potential method, parallel wire method, single electrode method), electro-magnetic methods; gravitational methods (torsion balance); seismic methods; radio-active methods; geothermal methods. A Chair of Geophysics has been established at the Imperial College of Science, South Kensington. These methods of prospecting for minerals have come increasingly into use of late years, and have been found of service in the work of geological surveying.

BLASTING.

Explosives are divided into low explosives, with a slow rending action and fired by simple ignition, and high explosives, with a rapid shattering action, fired by means of a detonator. The rate of explosion of gunpowder, typical of the former, is 3 to 4 metres per second, and of blasting gelatine, typical of the latter, up to 7,000 metres per second.

For blasting in fiery coal-mines explosives known as safety explosives are employed, which have a lower temperature of detonation. No explosive can, however, be considered really safe in a fiery atmosphere. A shot-hole in coal should never be placed in the solid, i.e. in coal that has not previously been undercut.

If D be the depth of a properly placed shot-hole, the volume of rock blasted out averages with one free face $0{\cdot}37\ D^3$; with two free faces volume $= 0{\cdot}84\ D^3$, and with three free faces $1{\cdot}33\ D^3$. In drifting and shaft sinking the volume blasted out is approximately $0{\cdot}75\ D^3$. If L be the line of least resistance, D = about 1·75 L.

The quantity of explosive required for charging a shothole is determined by experience and though formulae exist (notably that of Chalon and its modifications) small reliability can be placed upon them in practice.

* See 'The Valuation of Alluvial Deposits,' by W. R. Rumbold. *Trans. Inst. Min. Met.* 2nd edn.), vol. xxxvii, 1928, p. 437.

† See 'Applied Geophysics,' by A. S. Eve and D. A. Key, Cambridge University Press (1st Edn.), 1929; also papers *Trans. Inst. Min. Eng.*, vols. lxxxvi and lxxxix, and 'Scope of Geophysical Prospecting' in 'Free State and New Rand Gold,' by D. Jacobsson, 1945.

Low tension detonators are best in series, high tension in parallel. Electric detonators are generally fired by magneto-exploders. Certain explosions are being attributed to faulty exploders, and dry batteries are being recommended in the place of exploders. (*Trans. Inst. Min. Eng.*, vol. lxxxiii., p. 222.)

Electric detonators consist of a fuse-head electrically fired, which communicates the ignition to an ordinary detonator. The fuse-head is generally contained in a paper tube, the empty space being filled with molten sulphur and the fuse-head cemented by a waterproof cement into the detonator. Electric detonators are distinguished as low tension and high tension; the low-tension fuse-head has a resistance of 0·9 to 1·3 ohms., the high tension 1,500 to 50,000 ohms, which, by bad treatment, may be reduced to as low as 50 ohms. Some makers make a fuse-head with an intermediate resistance of about 100 ohms. In the low-tension detonator the terminals of the copper wire leads are connected by a piece of fine wire, which the passage of the current heats to redness, whilst there is no such wire in the high-tension fuse-head. The wire consists of an alloy of copper, manganese and nickel, and the fuse-head proper in a low-tension fuse consists of copper acetylide, whilst in the high tension it is a mixture of this substance and graphite. In both types of fuse the fuse-head terminates with a mixture of chlorate of potash and carbon, which gives a flame to ignite the detonating composition. The low-tension fuse requires current of at least 0·4 amp. to fire it.

Liquid air is used in the ironstone mines of Lorraine; a cartridge containing sawdust, powdered cork, soot, or a similar substance impregnated with liquid air or liquid oxygen is employed. No detonator is required, but the shot must be fired within 15 minutes of charging. The addition of aluminium powder to the charge greatly increases the detonating action. The quantity of liquid air used is 0·3 litre per ton of ironstone, and the cost of this explosive per ton blasted is given as 0·303 per cent. as against 0·571 per cent. with cheddite and 0·597 per cent. with compressed black powder. Liquid oxygen is preferred to liquid air, because the latter is apt to produce fumes containing oxides of nitrogen which injuriously affect the miners, whereas with the former no noxious gases at all are evolved. It has also been used in some of the Lincolnshire * ironstone quarries.

Under Explosives Order No. 1194 of 1921, the production in the mine of an explosive by impregnating carbonaceous material with liquid air or oxygen is permitted under licence, thus modifying Section 50 of the Explosives Act, 1875. (See p. 951.)

STEMMING.

Stemming, also known as tamping, is the act of closing the shot-hole with some material which is intended to resist the action of the charge of explosive. A 'blown out shot' is one in which the stemming is projected from the shot-hole. Coarse sand makes an excellent stemming material. (See *Trans. Inst. Min. Eng.*, vol. lxxxii., p. 497, and vol. lxxxiv., p. 298.)

Professor J. A. S. Ritson suggests the use of sand and clay well mixed with calcium chloride. (See *Trans. Inst. Min. Eng.*)

SHEATHED EXPLOSIVES.

The late Professor Wheeler showed that the production of flame is not instantaneous but is the result of a series of reactions and that certain substances can delay or even inhibit one or other of these intermediate reactions.

Cartridges sheathed with a thin layer of sodium bicarbonate which acts as a cooling agent, thereby rendering the flame of the explosive less incendive, rather than as an 'inhibitor.' (See 'Sheathed Explosives,' by C. A. Naylor and R. V. Wheeler, *Trans. Inst. Min. Eng.*, vol. lxxxvi, p. 345.) These 'sheathed' explosives are now very largely in use in gassy and dusty collieries.

Detonators.

Detonators.—These are known by numbers, the charge of which varies somewhat. The following is about the average practice:—

Detonator numbers . . .	1	2	3	4	5	6	7	8
Weight of mixture in grains .	$4\frac{1}{2}$	6	8	10	12	15	23	30

The mixture consists of 80 per cent. fulminate of mercury, 20 per cent. chlorate of potash. Tetryl and Lead Azide mixture are also now used. (See *Proc. Roy. Soc. N.S.W.*, vol. lxiii, p. 85.)

Detonating Cord (Cordeau détonant) consists of a flat tube of lead, tin or aluminium usually 7 mm. wide, 3 mm. thick, filled with nitro-methylaniline or trinitrotoluol, containing usually about 10 grams of explosive per metre. An explosion is propagated through this at a velocity of about 7,000 metres per second. A piece of this cord is attached along a row of blasting cartridges and ensures their complete and instantaneous detonation, even in wet holes. It is stated that the efficiency of the explosive is increased by 20 per cent., and that experiments at

* *Journ. Iron and Steel Inst.* vol. cxvii., 1928; Pt. I., p. 186.

Lievin have shown that an explosive mixture of firedamp is not ignited by the detonation of 3 metres of cord.

Ordinary fuse burns at the rate of 30 seconds per foot.

(See also Explosives, p. 949.)

Elimination of Misfiring of Centre Shots.

As a means towards the elimination of misfiring of centre shots in large-scale blasting in coal mines, the United States Bureau of Mines recommends that the following practices be used whenever shots are to be fired in wet holes: Use waterproofed electric detonators with enamelled leg wires. When making connections with enamelled leg wires, care must be taken to scrape the ends of the wires well, otherwise the enamel will prevent good electrical contact. Fire the shots from an ungrounded power circuit that has a capacity of at least 30 kw. Use extra care when tamping the holes in order not to damage the insulation of the leg wires. Arrange the connections between the detonators so that they are supported clear of the earth or any other conducting medium. (See *Technical Publication* No. 257, *Amer. Inst. Min. Met. Eng.*, 1929.)

In England the firing of several shots simultaneously, except in the case of Cardox, which is not an explosive, is forbidden, although several authorities consider this the safer method of working.

'Safety Explosives.'

Safety explosives, or Sprengel explosives, are a group of explosives consisting essentially of ammonic nitrate with some organic substance. Other safety explosives consist of various ordinary explosives to which some substance is added to reduce the energy or temperature of the explosion. In this country no explosives may be used in collieries that can be considered 'fiery,' unless they have passed certain prescribed tests, when they are known as 'permitted explosives.'

A new type, though not really an explosive, known as Cardox, has been introduced; it consists of a steel shell charged with liquid carbonic acid which is converted into a gas producing very great pressure by means of a heater ignited by an electric current. The Cardox method of mining coal has for some time past been largely practised in U.S.A., and has recently been increasingly applied in Great Britain, both because of the safety of its use in 'fiery' mines and of the saving effected by the production of a higher percentage of 'large' coal as compared with that produced by other methods. (See 'The Cardox Method of Mining Coal,' published by Cardox (Great Britain), Ltd. 20 Copthall Avenue, E.C. 2.)

'Low density' explosives are being introduced with the object of getting among other presumed benefits a lower speed of explosion. (See *Trans. Inst. Min. Eng.*, vol. lxxiii., p. 216, vol. lxxvi., p. 305, and vol. xci., p. 127.)

SHAFTS.

(See 'Vertical Shaft Sinking' by E. O. Forster Brown, 1927, and vol. ii. of 'Modern Practice in Mining: The Sinking of Shafts,' by Sir R. A. S. Redmayne, K.C.B., third edition.)

Modern shafts are generally either rectangular or circular in cross-section; the former are used in sinking upon narrow veins or seams, where the ground is not very heavy nor the amount of water excessive, or where good timber is cheap; under other conditions round shafts are preferred, but local custom also exercises much influence. Inclined shafts are practically always rectangular; elliptical shafts have been sunk in some places (Forest of Dean) but are now rarely used.

Rectangular Shafts.

Rectangular shafts for large mines may be up to 25 ft. long by 15 ft. wide in the clear. Exceptionally large shafts are used in Pennsylvania, e.g., No. 5 Wilkesbarre anthracite mines, 52 ft. by 12 ft., Exeter Red Ash, 46 ft. 2 ins. by 13 ft. 10 ins.

Round shafts, say from 8 ft. to 24 ft. diameter in the clear; a colliery shaft to wind **1,000 tons per day is usually 16 to 18 ft. diameter.**

Rectangular shafts are mostly wood-lined; they are either cribbed or timbered with sets **holding lagging in place. In Fifeshire shafts up to 30 ft. by 12 ft. are cribbed with** 'barring' **of 9 ins. by 3 ins. up to 6 ins. by 12 ins. The timber for a shaft 23 ft. by** 8 ft., including buntons, **etc., would amount to about 125 cubic feet, and would cost, including nails,** wedges, etc., **about 18*l*. 10*s*. per fathom. The cost of sinking (the ground is usually easy) and putting in the timber is about 30*l*. per fathom. In the iron-ore mines of Cumberland and Lancashire shafts about 10 ft. by 5 ft. are cribbed with 10 ins. × 5 ins. plank, the ends being half checked; the total cost including sinking, timbering, timber, stores, etc., is about 30*l*. per fathom, the ground being carboniferous limestone that requires blasting. Sets are made of squared timber 4 ins. × 6 ins. for a small shaft, up to 9 ins. × 15 ins. for a very large one; sets are 3 ft. to 6 ft. apart, held together by hook bolts of 1½-in. round iron with wing nuts.**

Horned sets or bearer sets are put in about every 6 sets or so, depending on the nature of the **ground; lagging is often 9 ins. × 3 ins. plank.**

Round Shafts.

Round shafts are lined with brick or concrete in ordinary strata; special methods are adopted where shaft traverses water-bearing strata and the lining is required to keep back water. For shafts over 18 ft. in diameter ordinary brick may be used; for smaller shafts wedge bricks should be employed. Let f be the width of the inner face of the brick, b of the outer face, l the length of the brick and R the radius of the shaft. Then $b = \frac{(R + l)f}{R}$; if, as is often the case, $l = 2f$, this becomes $b = f + \frac{2f^2}{R}$. Instead of bricks, firebrick lumps 6 ins. to 8 ins. × 12 ins. to 18 ins. × 10 ins. to 15 ins. may be used. They should also be made wedge shaped in accordance with the above formula. A shaft 10 ft. in diameter lined one brick thick requires about 350 bricks laid in mortar, per foot of depth. The thickness of the lining depends on the nature of the ground and the diameter of the shaft.

COST OF SINKING.*

The cost of sinking may be taken as made up of five main items: Supervision, labour, materials, power, and interest on capital expended.

Walling, including the cost of the bricks, amounts to between 15*s*. and 30*s*. per cubic yard of brickwork. Walling a shaft 13 ft. in the clear, 15 ft. over all, cost about 15*l*. per fathom = 30*s*. per cubic yard; walling a shaft 22 ft. in the clear, 25 ft. over all, cost 24*l*. 5*s*. per fathom = 15*s*. 6*d*. per cubic yard. A walling curb costs about 10*l*. Sinking a shaft 12 ft. in the clear cost 24*l*. per fathom (sinkers and waiters-on, 13*l*. 10*s*.; general labour, 7*l*. 10*s*.; explosives and stores, 3*l*.). Sinking a shaft 13 ft. in the clear costs 23*l*. to 30*l*. for labour in ordinary strata, and 70*l*. to 100*l*. in basalt, per fathom.

A rough and ready rule for estimating the cost of sinking and walling circular shafts of from 18 to 21 ft. in diameter through ordinary coal measure strata, in which little water is encountered, is to allow £2 per ft. diameter per yard in depth. This is inclusive of cost of labour, hammer drills, tools and explosives, but exclusive of walling material.

The following are the particulars as to cost respecting a shaft of finished diameter 16 ft. which commenced sinking in September 1929 and finished September 1932. The shaft was sunk to a depth of 738 yards through ordinary coal measures in North Staffordshire. Progress while working one shift was about 4 yards a week and while working two shifts 8 yards a week. Most of the work was done working one shift per diem. Shaft lining was of brickwork, 14 ins. thick, set on oak curbs concreted into the solid to hold each length of brickwork independently, average length of bricking in each length approximately 18 yards.

Cost per yard sinking	£16.
Bricking	£3 10*s*.
Cost of material in shaft	£6,647.
,, ,, Steel headgear	£890 erected.
,, ,, Pulleys and bearings	£260
,, ,, Guide ropes (8) (half lock coil)	£1,844
,, ,, Winding ropes (2)	£865
,, ,, Cages (2)	£406
,, ,, 30″ × 6″ Markham (termed secondhand) winding engine	£1,500

The cost per yard for wages and materials was just under £30.

Most of the feeders of water were cemented off with liquid cement pumped in at a pressure of 100 lbs. per sq. in.

The contract price of £16 per yard included provision of a winding engineman and banksman and the handling of the dirt at the surface and putting it into its final position. This may be taken as a highly satisfactory result even though it was an instance in which little water was encountered.

The cost of sinking and tubbing a section of 22-ft. shaft at Blackhall, with feeders of water from 300 to 2,885 gallons per minute, was as follows:—

	£	*s*.	*d*.	
Underground labour	70	10	10	**per linear yard.**
Surface ,,	26	13	7	
Materials, coal and stores	87	2	1	
	£184	6	6	

* Under conditions at present existing, *e.g.* high wages and high cost of materials, the figures quoted under this heading would have to be materially increased in order to be severally applicable for 1949.

The cost of sinking a 22-ft. shaft through limestone and tubbing it, against feeders of water averaging 3,000 gallons p.m., may be averaged at about 275*l.* per yard of depth.
(*J. J. Prest*, Tr. Inst. M. E. xlvii. p. 611.)

Shafts may be lined with cement, either by setting sheet iron cylinders and ramming concrete round these, lifting the cylinders when the cement has set, or by walling with thin blocks or slabs (about 2 ft. 6 ins. × 3 ft. 6 ins. × 5 ins.), and ramming cement behind this facing ring. The cost of an 18-in. monolithic lining in a 22-ft. finished shaft was made up as follows :—

	s.	d.	
Mixing concrete	1	0	per cub. yd.
Cement	4	2	"
Lining shaft with concrete	2	6	"
Coal and stores	0	9	"
Steel cylinders and other plant	1	4	"
Total	9	9	per cub. yd.

There were 28 cubic yards to the fathom, hence the cost per fathom was 13*l.* 13*s.* It took seven hours to complete the concreting of one fathom.

The cost of walling a similar pit with brickwork was 24*l.* 3*s.* 3*d.*

Lining a 22 ft. shaft at Blackhall with a monolithic cement concrete (6 : 1) lining cost per linear yard :—

	£	s.	d.
Labour in loading sand and gravel	1	18	6
Enginemen and attending mixer	0	4	1
Cement	3	13	6
Interest and depreciation on shuttering, etc.	0	19	0
Coal, stores, etc.	0	10	6
Labour in shaft	3	1	7
	£10	7	2

Lining with concrete blocks 3 ft. 6 ins. × 2 ft. 6 ins. × 5 ins. backed solid by ramming in concrete, all also 6 : 1, cost practically the same. The average cost of sinking and walling with 18 in. concrete was 26*l.* 1*s.* 8*d.* inclusive. Suitable bricks would have cost 45*s.* per 1,000, and at this price brickwork in cement would have cost 15*l.* per running yard. (*Loc. cit.*)

In a 14 ft. pit the total costs of labour for sinking and concreting came to 15*l.* 15*s.* per fathom. The cost of the concrete was about 21*s.*, and the labour of lining the shaft with it about 1*s.* 6*d.*, or altogether 22*s.* 6*d.* per cubic yard. There were 10½ cubic yards per fathom, so that the cost of the concrete lining amounted to 11*l.* 16*s.* per fathom ; with four men at the surface and four men in the pit, the concrete was put in at the rate of a fathom in six hours. At Karwin, Silesia, an 18 ft. shaft was lined with concrete put in from above downwards at the rate of a fathom in fourteen hours at a cost of 62*l.* per fathom complete ; the same shaft lined in the upper part with brickwork had previously cost 132*l.* per fathom. Ferro-concrete has been used in place of simple concrete. At Zweckel, near Gladbeck, a shaft was lined with ferro-concrete slabs backed with concrete, into which the iron framework of the slabs was continued, for 23*l.* per fathom. At Rheinelbe a shaft 20 ft. in diameter was lined with Monier ferro-concrete 11 ins. thick at a cost of 2*l.* 5*s.* 6*d.* per cubic metre of lining, or 30*l.* 12*s.* per fathom of shaft : for a similar shaft at the Hansa Colliery lined 9½ ins. thick the prices were 2*l.* 3*s.* 6*d.* per cubic yard or 29*l.* 14*s.* per fathom.

Shaft Lining.

In heavily watered strata a lining has to be put in strong enough to resist the pressure of water. The thickness of such lining may be calculated as follows :—

Let R be the internal radius of the shaft, s the maximum admissible stress in the wall, p the pressure to be resisted, all to the same units, which are preferably inches and pounds, then :—

$$\text{Thickness of wall} = R\left(\sqrt{\frac{s}{s-2p}}-1\right)$$

(*Aldis*, N.E. Inst. M. E. xxxii. p. 201.

The resistance to crushing of the various materials used in lining shafts is :—

Common brick	800 to 1,000 lbs. per square inch.
Fire brick	1,500 to 2,000 " " "
Sandstone	1,500 to 5,000 " " "
Concrete 1 : 3 : 6 to 1 : 1 : 3	2,000 to 5,000 " " "
Average	3,000 " " "
Cast iron	90,000 to 120,000 " " "

Safe loads may be taken as $\frac{1}{10}$ of these ; for best brick laid in 1 : 3 Portland cement up to 250 lbs. ; for ferro-concrete up to 600 lbs. per sq. in. ; for frozen sand fully saturated with water at −12° C. up to 340 lbs. per sq. in. (*Alby*, Bull. Soc. Ind. Min. 1895, p. 273.) L. Sauvestre has shown that frozen sand is highly plastic, and that its resistance to crushing increases by 28½ lbs. per sq. in. for each drop of 1° C. (*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I, p. 5.)

The pressure to be resisted is usually taken merely as the head of water—namely, 0·434 h lbs. per sq. in., where h is the head expressed in feet. For quicksands Poetsch adopts a formula equivalent to $p = 1{\cdot}042\ h \tan^2\left(45° - \frac{\alpha}{2}\right)$, where α is the angle of repose of the sand; Poetsch gives $\alpha = 35°$ for fine quicksand, and 20° for coarse sand. These figures are used in calculating the thickness of the ice-wall required in the freezing method of sinking.

Many approximations are used for ordinary shaft linings :—

J. J. Atkinson : Thickness in inches $T = \frac{5{\cdot}2\ R\ h}{s - 0{\cdot}434\ h}$, or for cast iron $T = \frac{5{\cdot}2\ R\ h}{9{,}000 - 0{\cdot}434\ h}$.

Chaudron: for cast iron, $T = 0{\cdot}8 + \frac{0{\cdot}434\ R\ h}{600}$ where $h < 165$ ft. and $T = \frac{130}{h} + \frac{0{\cdot}434\ R\ h}{600}$ where $h > 165$ ft. (here s is taken at only 7,200).

Riemer takes $s = 11{,}400$, and writes :—

$$T = 0{\cdot}8 + \frac{0{\cdot}434\ R\ h}{950} \text{ for } h < 165,$$

$$\text{and } T = \frac{130}{h} + \frac{0{\cdot}434\ R\ h}{950} \text{ for } h > 165.$$

Cast-iron tubbing is always stiffened by ribs and flanges, and these should be taken into account. (See *Morrow*, *Trans. Inst. Min. Eng.*, xxxiv., p. 100.)

Coffering.

Coffering may be used for moderate pressures and shallow depths ; costs range from 20*l.* 10*s.* per fathom (16-foot shaft) to 38*l.* per fathom (18-foot shaft), being considerably less than cost of cast iron tubbing.

Tubbing.

Tubbing is put in either by English or German method ; in the former, segments are 2 ft. to 3ft. deep, flanges are external, not machined, and the joints are made with wood sheeting and wedges ; in the latter, segments are 5 ft. to 6 ft. deep, flanges are internal, are machined, and the joints are made with lead sheeting and bolts. In both forms the tubbing is carried upon wedging curbs, followed usually by a foundation ring. In some few recent cases the wedging curb the been dispensed with, and the tubbing set direct upon a good bed.

Cost of Tubbing.

Cost of English tubbing varies with the price of pig iron, etc., from 5*l.* to 7*l.* 10*s.* per ton ; putting in the tubbing costs 2*l.* to 2*l.* 10*s.* per ton of tubbing put in, or 5*l.* to 7*l.* per fathom of shaft. The following are the detailed costs of tubbing a 15 ft. shaft with 12 segments to the ring, 2 ft. deep, ⅜ in. thick, each ring weighing 2 tons 10 cwt. :—

	£	s.	d.
Three rings, 7 tons 10 cwt. at 7*l.* 10*s.*	56	5	0
Sheeting, 213 ft. at 8*s.* per 100	0	17	0
Wedges, 3,500 at 10*s.* per 1,000	1	15	0
Labour, putting in and wedging	6	0	0
Total	64	17	0
Cost per fathom, about	64	0	0

To the above must be added a due proportion of the wedging curb. The castings for the curb of a 15-ft. shaft cost 25*l.* to 35*l.*, sheeting and wedges 5*l.*, putting in and wedging 10*l.* to 15*l.* Dressing the curb seat may cost from 10*l.* to 40*l.* according to circumstances. About ten men are usually employed in the shaft in wedging tubbing, and they can wedge two to three rings per shift.

The cost of 'German' tubbing usually comes out a little less than English tubbing per fathom. The seams and joints are all machined, this costing 3*l.* 10*s.* to 4*l.* per ring ; three shifts of four men can put in and bolt up four rings (20 to 24 ft.) per 24 hours.

The cost of 'German' tubbing in an 18-ft. shaft, the tubbing being 1 in. to 1¼ in. thick, 2 segments to the ring 5 ft. deep, was as follows in this country :—

	£	s.	d.	
Cast-iron tubbing, 13 tons 4 cwt. at 7*l.* 10*s.*	99	0	0	per fathom
Lead for sheeting and washers, 6 cwt.	6	0	0	
Bolts and nuts	3	5	0	
Labour	7	10	0	
Cost per fathom	115	15	0	

In the Minister Achenbach Colliery a shaft 17 ft. in diameter was tubbed with 18 rings of tubbing 8 ft. 2 ins. high, 1 in. to $1\frac{1}{4}$ in. thick, each ring composed of 10 segments. The weights of material employed were:—

Tubbing . . .	192 tons 10 cwt.	Lead washers . . .	1 ton 2 cwt.
Lead strips . .	2 „ 8 „	Bolts, nuts and washers .	6 „ 3 „

Where the ground is weak and apt to run, suspended tubbing can be used to much advantage. This method was used at Astley Green (*Trans. Inst. Min. E.*, xxxix. p. 543), also at Hamsterley (*Trans. Inst. Min. E.*, xxxviii. p. 320); the latter shaft was 10 ft. in diameter and 35 ft. deep. The cost was:—

Materials, 627*l.* 2*s.* 10*d.*, labour, 141*l.* 0*s.* 3*d.*, equal to 83*l.* 16*s.* per fathom. The method is to be recommended for safety, speed and economy.

Of late years cast iron with a small proportion of molybdenum has been found advantageous for tubbing. Where extremely heavy pressures have not to be resisted, ferro-concrete may be used and has been used in several cases. The cost of ferro-concrete tubbing resisting a pressure of some 800 lbs. per sq. in. for an 18-ft. diameter shaft is calculated at about £22 per lin. ft.

All forms of shaft lining are apt to suffer by corrosion, especially in many cases at the outer skin where the shaft traverses water-bearing strata in which the water contains salts in solution that are capable of attacking the lining. Galvanic action can also produce corrosion, and such action may be set up by the not uncommon method of tightening the joints in German tubbing by means of copper wire. In iron tubbing a layer of rust is apt to form, but this should be removed from the interior of the shaft as promptly as possible, because it is injurious to the underlying tubbing and does not form a protective layer as is often supposed. Brickwork is readily destroyed by corrosion, but as it is rarely used to line shafts through water-bearing strata, this is a matter of secondary importance. Neither concrete nor ferro-concrete can be expected to remain permanently water-tight, and both are very liable to corrosion. The best form of tubbing to resist corrosion is apparently double tubbing with concrete between the two cast-iron skins.—'Glückauf,' vol. lxix., p. 161.

The above, which may be called ordinary methods of sinking, can only be used where a moderate influx of water has to be contended with; the greatest quantity ever dealt with by these means has been in the sinkings at Blackhall Rocks, where the Horden Colliery Company has sunk two shafts through the Magnesian Limestone in which 14,300 gallons per minute were being pumped from a depth of about 90 yards. Very much less than this is generally sufficient to cause special methods to be resorted to, 5,000 gallons per minute being generally considered prohibitive.

Cost of Shaft Sinking in Gold Mines.

A shaft 4 ft. by 8 ft. in clear can be sunk in California, where wages are 14*s.* per shift, by hand drilling, at a cost of 4*l.* 10*s.* per foot. This includes labour, timbering, explosives and supplies. The hoisting done by a horse whim and no water to pump. The rate of progress is about one foot per day.

In Nevada a shaft 4 ft. by 8 ft. in clear was sunk 100 ft. in $31\frac{1}{2}$ days by means of hand drilling. The cost per foot was 6*l.* 10*s.* Labour 16*s.* per shift.

In Western Australia shafts vary from 4 ft. by 10 ft. to $5\frac{1}{2}$ ft. by $13\frac{1}{2}$ ft. On eleven of the mines in the district the cost per foot of shaft is from 11*l.* to 16*l.*, and from 2*s.* 9*d.* to 5*s.* 6*d.* per cub. foot of material excavated. The average monthly advance was 34 ft. to 60 ft. with an average of 50 ft. Machine drills used on all above shafts.

See 'Cost of Sinking the East Shaft of the New Kleinfontein Company, Limited,' by H. J. Way, *Trans. Inst. Min. Met. Eng.*, vol. xiii, 1903–04, p. 102.

In Utah, with wages 12*s.* per shift, a shaft 17 ft. by 65 ft. was sunk in ground of medium hardness at a cost of 12*l.* per foot sunk or 1*l.* 16*s.* per ton of material broken. Machine drills used. Pumping from 800ft. Rate of sinking 0·9 ft. per day.

On the Rand a shaft (Brakpan, Ltd.) 43 ft. by 9 ft. in the clear was sunk at a rate of 204 ft. per month. The working cost was 14*l.* 10*s.* per foot and the total cost 22*l.* 14*s.* per foot. Ground soft. Hand drilling employed.

The following are some of the Rand shafts and the cost per ton of material handled:—

Shaft.	Size.	Speed per Month.	Cost per Ton.	Method Employed.
			s. *d.*	
Rand Collieries . .	34 ft. by 9 ft.	120 ft.	10 9	Machine
Kleinfontein . .	34 ft. by 9 ft.	107 ft.	11 3	„
Brakpan . . .	43 ft. by 9 ft.	124 ft.	8 11	Hand.
City Reef	46 ft. by 9 ft.	125 ft. 6 ins.	9 2	„
Hercules . . .	47 ft. by 9 ft.	119 ft.	8 5	„
Wolhunter . . .	46 ft. by 9 ft.	95 ft.	10 6	„

The Inspiration Copper Company, Miami, Arizona, sunk and completed a shaft 12 ft. 4 in. by 16 ft. 8 in., 1,400 ft. deep in 10 months.

Some exceptionally fast sinking has been done on the Rand; thus, in one of the shafts on the Crown Mines 318 ft. were sunk in August, 1925, and in one on the Randfontein Estates 386 ft. were sunk in June 1926.

Winzing and Raising.

At Park City, Utah, winzes 11 ft. by 7·5 ft. in quartzite are sunk at a cost of 6*l*. per foot sunk, or 1*l*. 10*s*. per ton of material broken. The advance is about 1 ft. per day. In same mine raises, 17·5 ft. by 5·5 ft., are put up at a cost of 1*l*. 14*s*. per foot or 4*s*. per ton of material broken. The advance is at the rate of 3·3 ft. per day.

In Western Australia winzes are from 4 to 5 ft. in width and 6 to 8 ft. long. They are 50 ft. to 200 ft. deep, and the average total cost per foot in eleven of the mines is 4*l*. 15*s*.

The rises in the same district extend from 25 ft. to 120 ft. in height, and are 4 ft. to 5 ft. wide and 6 ft. to 8 ft. long. The total cost on the average is 3*l*. 18*s*. 7*d*. per foot.

Special Methods of Sinking.

In hard, very wet ground :—

Kind-Chaudron : maximum diameter of shaft, 15 ft.; greatest depth yet attained by it, 1,335 ft.; Nos. 1 and 2 pits Marsden Colliery (the first successfully sunk in this country by this method) cost respectively 362*l*. 8*s*. and 293*l*. per fathom; in the North of France shafts 8 to 12 ft. diameter to depth of 100 fathoms cost 80*l*. to 240*l*. per fathom, and the rate of sinking varied from 2 to 6 fathoms per month. In Germany it is estimated that to sink 55 fathoms by this process at a depth of about 300 fathoms would cost about 1,400*l*. per fathom for a shaft 14 ft. 6 ins. in diameter. (See *Bull. Ind. Min.*, 1909, ser. 4, vol. ii, p. 342.)

*Poetsch Freezing Process.**—Applicable both to fissured firm ground and to running ground. The brine used is a 25 per cent. solution of magnesium chloride cooled down to − 20° C., its freezing point being about − 35° C. The following table shows the pressure at which ammonia gas liquefies at different temperatures :—

Temperatures.		Pressures in Lbs. per Sq. In.
−20°C.	− 4°F.	27
−10°C.	+14°F.	41
0°C.	+32°F.	62
+10°C.	+50°F.	89
+20°C.	+68°F.	125

It is estimated that to produce 100,000 negative calories per hour at —15 C., 50-60 h.p. are required at the freezing plant, and that 0·25 lb. of ammonia and 2 gallons of brine are required for each yard in length of the freezing circuit.

Saturated sand (165 parts water to 1,000 parts sand) frozen at 32° F. has a crushing strength of 242–341 lbs. per sq. in., and at − 13° F. of 2,845 lbs. per sq. in.

Shafts have been sunk to 130 fathoms by this method, the cost for shafts 13 ft. to 16 ft. in diameter ranging from about 150*l*. to 250*l*. per fathom. The cost of sinking two pits, 12 ft. and 15 ft. 6 ins. respectively in diameter, at Ansin, in 1895, to a depth of 50 fathoms, was as follows :—

	£ s. d.	£ s. d.
Cost of freezing plant		73 2 0
Cost of freezing operations		48 6 0
Cost of sinking and tubbing : labour .	32 16 0	
Cost of tubbing . . .	66 10 0	
		99 6 0
Total cost per fathom		220 14 0

The cost of sinking a pair of 20 ft. shafts by freezing under ordinary conditions should be :—

	£
To a depth of 50 fathoms	17,500
„ „ 100 „	28,000
„ „ 200 „	50,000

(*W. W. Wilson*, Tr. Inst. M.E. xli. 353.)

* See *Rev. Univ. d. Min.*, 1931, p. 185.

Freezing an 18-ft. shaft at Monkwearmouth cost 230*l.* per fathom to a depth of 60 fathoms.

A deep sinking was carried out by this process at Beeringen in 1920; a depth of 1,640 ft. of clay, quicksand, and water-bearing chalk was first sunk through in this way, and subsequently the process was applied to the more difficult task of passing through a bed of running sand 46 ft. thick, at a depth of 2,000 ft. under a pressure of 926 lbs. to the sq. in.

(*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I. p. 5.)

At Seaham, Co. Durham, there were three freezing units, one of 300,000 negative calories and two of 150,000 negative calories each per hour (300 and 150 h.p. respectively). There were five double-acting brine pumps 10 in. diam., 10-in. stroke; the brine was calcium chloride solution of sp. gr. 1·25. Two shafts have been sunk 21 ft. diam. in the clear to a depth of about 490 ft. The freezing was carried out in sections by a method which the inventors call the 'rational' method, which has also been applied with much success in the Campine, Belgium. (See *Ann. d. Min. Belg.*, vol. 22, 1921, p. 535; 'The Sinking of Londonderry Colliery, Seaham Harbour, Co. Durham, by the Freezing Process,' by J. L. Henrard and J. T. Whetton, *Trans. Inst. Min. Eng.*, vol. lxxv., 1928, p. 358.)

In the sinking of No. 19 pit at Courrières in 1909, which was sunk by the freezing method, difficulties were encountered in the upper part of the shaft owing to running water, and these were overcome by the injection of cement to a depth of 57 ft.; over 1,000 tons of cement were used. (*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I. p. 38.)

In sinking through strata containing brine, *e.g.* in certain potash mines, the temperature must be reduced below − 35° C. Liquid carbonic acid must be used instead of ammonia in the freezing plant and calcium chloride brine. (*Glückauf*, vol. 63, 1927, p. 293.)

Sheet piling can be used for relatively shallow sinking, near the surface. At Bowburn Colliery Co., Durham, 6 fathoms of wet sand were sunk through by wooden piles in 1906 at a cost of 26*l.* per fathom for timber and 34*l.* 10*s.* for labour. Interlocking steel piling of joists of various forms has also been used.

The dropshaft method is employed in various forms, sometimes by weighting a cutting shoe and curb, on which an iron or brickwork cylinder is built up, or more usually by building a brick or concrete pressure block against which work hydraulic rams that force down tubbing of cast iron, or in exceptionally difficult cases of cast steel. The former method (forcing down a shoe by dead-weight) was found much superior to forcing a shoe down by jacks in sinking a shaft 14 ft. by 8 ft. through 70 ft. of loose strata at Des Moines, Iowa (*Trans. Amer. Inst. Min. Eng.*, vol. iv., p. 232). The following table shows probable costs for shafts of normal size in ordinary running ground (Hoffman):—

For depth.	Cost per fathom sunk. £	For depth.	Cost per fathom sunk. £
From 15 fathoms to 27 fathoms .	320	From 82 fathoms to 110 fathoms .	1,280
" 27 " to 55 " .	732	" 110 " to 137 " .	1,554
" 55 " to 82 " .	1,006	" 137 " to 165 " .	1,830

A sinking with a timber drop shaft lining is described in the February, 1922, *Bulletin of the Canadian Institute of Mining and Metallurgy.*

The *Honigmann* system has been used in a few cases down to depths of 70 fathoms on the Continent; the shaft is bored out by a dredge-borer, the walls being kept up by internal hydrostatic pressure, and the shaft is lined with tubbing composed of rings of channel iron riveted together and subsequently lined with concrete.

Cement Injections.—The Sonnenschein cementation process for sinking through quicksands consists in boring a number of holes about 5 m. deep, relatively close together, through the concrete plug in the shaft bottom. When a sufficient number of holes have been bored, water is forced down a bore-hole adjoining the one to be treated, thus forcing the quicksand up the latter, and leaving a conical cavity in the quicksand below the plug. Cement slurry is then forced down the borehole to be treated until the cavity previously formed is filled with cement, and the operation is repeated until a continuous body of cement, about 5 m. deep, is formed below the plug. The cement is then excavated until only enough is left to form a fresh plug, and the entire operation is repeated until the quicksand has been traversed.

The François Cementation Process.—The origin of the use of cement grout in mine shafts is not certain. Probably the first fully authenticated use was in the injection behind shaft lining at the Rheinpreussen shaft, near Homberg, in 1864, at a pressure of 210 lbs. to the square inch. Monsieur H. Portier at Courrières in 1900 successfully injected and sealed a considerable feeder of water behind an old shaft lining of wood. Cement injection was successfully employed at a shaft sinking in Germany by R. A. Weide, at Pohlhauer, Saxony, in 1901. Early examples of its use in France were by M. Reumaux at Lens; and by M. Deffieux at the Mine de Maries in 1908. In 1911 Mr. Albert J. François, who had previously spent some years on the Continent in experimenting with various systems of cement injection behind shaft lining and through various classes of strata, introduced his process into England. His process proved a valuable aid to the development and maintenance of coal mines in wet areas.

The process has since been introduced into France, Belgium, Germany and South Africa. In all, over forty shafts have been sunk by its means. The preliminary silicatisation

of the ground, which is an essential part of the process, was first tried at Hatfield Main, in 1911, with complete success. In porous or finely fissured strata, or alluvial deposits, or generally where the injection of cement slurry proves difficult, the preliminary preparation of the ground by the injection of solutions of silicate of soda and sulphate of alumina is used; the shaft is sunk by ordinary methods until the presence of water is indicated by means of test holes. A number of holes are then bored in the shaft bottom, pipes being cemented into them, their number, position and inclination being dependent upon the size of the shaft and the character of the strata. Through these pipes boreholes are sunk by means of a diamond drill. On the tapping of feeders by one of the holes the boring is immediately stopped and the pipe in the hole connected by means of a length of high pressure flexible hose to a column of pipes in the shaft, leading in turn to a cement pump and mixing tank on the surface. The holes are arranged in series for cementation and silicatisation, and into them cement pulp and mixtures of chemicals are pumped, the strength and proportion of the mixtures of chemicals, the percentage of cement, and the pressure employed being such as experience has shown to be best suited to the class of strata and pressure of water to be treated. The holes are cleaned out and reinjected or further deepened as necessary, the process being repeated with the various holes, boring and injecting of the different holes taking place simultaneously. The ground is treated in this manner until the desired length of ground has been rendered sufficiently watertight to allow mining and walling operations to proceed. The ground is excavated in the ordinary manner and reinforced concrete walling built up, any water not sealed off by the cementation of the boreholes being shut off by injections between the completed lining and the ground. On the walling being completed a second length of ground is excavated and walled, this procedure being continued till the water-bearing strata have been passed through. The lining employed through water-bearing or bad ground is ferro-concrete tubbing of monolithic construction. Cementation in ordinary ground will cost about 50*l.* per yard for a 20-ft. shaft (see *Transactions of Mining Engineers*, vol. liii., 1916, p. 22).

The process has been used in sinking a shaft 16 ft. in diameter at the Holditch Iron Mine, Chesterton, Staffs. The shaft is sunk through the water-bearing Keele strata to a depth of 632 ft., the upper bed giving off 30,000 gallons of water per hour. The total time occupied was 69 weeks, and the costs were 40*l.* 4*s.* 4*d.* for labour and 36*l.* 3*s.* 9*d.* for material per yard of finished shaft (1916–17), or together 76*l.* 8*s.* 1*d.*; it is estimated that sinking with underhung tubbing would have cost 91*l.* 4*s.* 8*d.* The shaft was lined with reinforced concrete. Cement for injection of boreholes 350 tons 13 cwt., for the concrete walling 998 tons 6 cwt., and for the injection of the walling 50 tons 10 cwt. (*A. Hassam and T. T. Mawson*, Trans. Inst. Min. Eng. lviii. p. 16.)

In porous sandstones *The François Cementation Co.* first injects separately solutions of silicate of soda and sulphate of alumina, and follows this up with cement. This process was used successfully at Hatfield Main, Thorne, etc. Two shafts were sunk successfully at Ollerton by this process.

For a more complete description of the process see paper by H. Standish Ball, *Proceedings of South Wales Institute of Engineers*, vol. xxxvi. No. 2, p. 111.

Mr. Eustace Mitton estimates the cost of sinking through the Bunter sandstone by cementation, including the installation of ferro-concrete tubbing to a depth of 200 yards for an 18-ft. shaft, at £350 per lineal yard. (*Midland Counties Institute of Engineers*, October 15, 1921.)

At two shafts at Harworth Main, where there was an indicated quantity of water of 3,000 gallons per minute, the shafts were rapidly and successfully sunk by the François process, with a total residual water in both shafts of 6 gallons per minute (see 'Harworth Sinkings,' *Colliery Guardian*, Nov. 17, 1922); while at two shafts recently completed at Ollerton Colliery, where the estimated amount of water was even greater than this, the shafts were sunk by the François process with an average of residual water of only two gallons per minute in each shaft. (See paper read by Mr. H. Eustace Mitton before the Institution of Mining Engineers (*Transactions*, vol. lxx.), November 4, 1925.)

The François cementation process was successfully employed in preference to sheet piling at Haugh Colliery, Kilsyth, Scotland, for sinking from the surface to some 6 fathoms in depth through running ground.

See also L. Souvestrie, *Annales des Mines*, 12th series; *Colliery Guardian*, Nov. 10, 1922; an article in the *Iron and Coal Trades Review*, Sept. 8, 1922; *Kropf, Industriebau*, Oct. 15, 1922; 'Cementation des Grès Vosgiens,' by F. Arguillère, *Rev. Ind. Min.*, Nov. 1 1927, p. 451. Papers by A. A. Barnes and J. R. Fox, *Inst. of Water Engineers*, June 1927.

The time required to cement a 20-yd. length of shaft in various rocks is as follows:

Bunter Sandstone	16 days	Limestone	18–19 days
Pennant Sandstone	16 ,,	Chalk	12 ,,

and the quantity of cement required per yard of 20–22 ft. shaft has been found to be:—

Pennant Sandstone	15 cwt.–3 tons	Bunter Sandstone	5 tons–6 tons.
Magnesian Limestone	2 tons–4 tons	Chalk	up to 4 tons.
Triassic Sandstone	3 tons–6 tons		

Where silicatisation is employed, the consumption of silicate of soda is 1½ to 5 tons per linear yd., and that of sulphate of alumina about half of this.

(*Vertical Shaft Sinking*, by E. O. Forster Brown, 1927, pp. 147, 148.)

Under special conditions when very rapid setting cement is required, 'ciment fondu' has been used in place of ordinary Portland cement, and in intensely cold ground a mixture of magnesia and magnesic chloride has been used.

LIST OF DEEP MINES* IN THE WORLD.

Mine.	Date (where known).	Locality.	Depth, Ft.	Mineral Wrought.

The greatest depth for a single wind is (over) 5,000 ft. at Valkfontein on the Rand.

The Barnsley Bed was cut in the Thorne sinkings at 2,765 ft. on August 22, 1924.

The deepest workings in the world at present are: the Robinson Deep Mine, deepest point 8,400 ft. below shaft collar; Morro Velho, St. John del Rey, 8,051 ft.

In 1924 the total depth of all shafts in mines in Great Britain coming under the C.M.R. Act was 845,000 yds., and the ratio of shaft yardage to average tons of daily output was 1 : 1·183; in the U.S.A. the ratio of output appears to be at least 15 times as great.

Shaft Pillars.

The 'draw' in ordinary Coal Measure strata, practically horizontal, is generally between 5° and 15° to the vertical. In Staffordshire 'draws' between 8° 45′ and 11° 10′ were observed in strata dipping 1 in 24 (W. Hay, *Trans. Inst. Min. Eng.* xxxvi. p. 47). The Final Report of

* In some of these the depth of a single shaft is given but in others the deepest part of the mine from the surface, e.g. the Morro Velho Mine, is worked by a series of shafts sunk from different levels in the mine and in the case of the Robinson Deep Mine there is a vertical shaft of 4,000 ft. which is fed by inclines. The deepest vertical shaft in South Africa is that at Vlakfontein. At the Crown Mines, also in South Africa, a depth of about 7,000 ft. is reached, but here again the arrangement is somewhat similar to that at Morro Velho in that a vertical shaft from the surface is fed by a sub-vertical shaft. At Pendleton in Lancashire the shafts are 1,530 ft. in depth, but owing to the dip of the measure to the south a depth of over 3,460 ft. from the surface is reached.

† *Mining and Metallurgy*. August 1932, p. 370.

the Coal Conservation Committee (Cd. 9084), 1918, p. 64, implies that the maximum angle of 'draw' to be expected is 26° 35′. In secondary strata the 'draw' is generally between 15° and 30°.

There are reasons for assuming that the angle of draw in practically horizontal strata approximates to $45° - \frac{\text{angle of repose}}{2}$. (See *Annales des Mines*, 1931, p. 211.)

In Westphalia (*Zeitsch. f. B. H. u. S. W.*, 1897) the draw in the Coal Measure has been found to be 15° on both rise and dip sides when the dip of the seam is < 15°; for dips exceeding 15°, the draw is 15° on the rise side and increases uniformly up to 35° on the dip side, reaching this value with seams dipping 35°. In the overlying clay deposits the draw is uniformly about 20°. The depth of subsidence is $kT \cos a$, where T is the thickness of the seam and a its inclination; k is a coefficient, which is 0·8 when the goaf is not stowed at all; with a well-stowed goaf, k is 0·4 when a is 0° to 10°, 0·3 when a is 10° to 35°, and 0·25 when a is 35°.

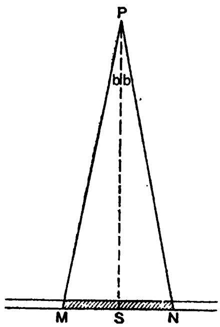

FIG. 1.

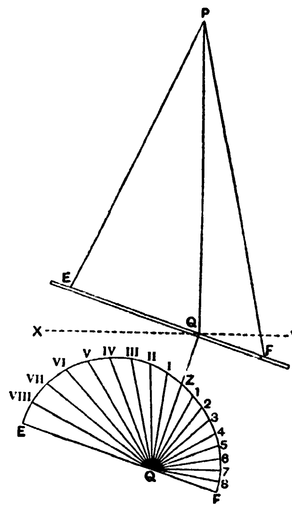

FIG. 2.

When a structure on the surface has to be protected from damage, a portion of the seam of coal or other mineral, usually spoken of as a pillar, has to be left unworked, and its position and dimensions must be calculated according to the draw. The simplest case arises when a single bed of mineral, lying horizontally, is worked out, and if the problem is to support a single point on the surface, obviously the pillar will be circular in plan, having a radius equal to D tan b, where D is the depth of the seam below the point to be protected and b the angle of draw. In fig. 1, PS = D, the depth of the seam, and SM or SN is the radius of the protecting pillar. It follows that if a number of seams one below the other are being similarly worked out, the pillars left in the lower seams will be progressively larger in proportion to the depth below the surface at which the seams occur. This method may be fairly well applied as long as the dip of the seam is less than 3°.

When the seam is inclined the position becomes more complicated, and is not thoroughly understood yet. The following may be taken as a general rule: Let b_l be the angle of draw on the lower side of the excavation, *i.e.*, on the rise side of the pillar, and let b_u be the angle of draw on the upper side of the excavation or the dip side of the pillar, b being the normal draw when the strata are horizontal

then

$$b_l = b + ckf(i) \text{ and } b_u = b - kf(i),$$

where i is the inclination of the seam of mineral measured in the usual way to the horizontal, c and k are coefficients, and $f(i)$ is some function of the inclination. This formula is purely empirical and should not be applied where i exceeds 30°; furthermore, $kf(i)$ can never exceed b.

Apparently $f(i)$ may be taken as sin i, k (in the coal measures) has approximately the value of 8, and c between 1·8 and 2.

Based on this formula, it is possible to calculate the dimensions of the pillar to be left in an inclined seam below a point on the surface which is to be supported, the depth of the seam below the point being, as before, D. It is easiest to calculate the dimensions of the pillar in the plane of the seam, and these can readily be projected on a horizontal plane if required.

The length (in the plane of the seam) of the pillar in the direction of full rise is given by the expression $D \sin b_l / \cos (b_l - i)$ and in the direction of full dip by $D \sin b_u / \cos (b_u + i)$, whilst the width at right angles to the dip will be $D \tan b$ on either side of the centre. Intermediate points must now be calculated as shown in fig. 2, where P is the point to be supported, Q being a point in the seam vertically beneath it. QZ is drawn in the line of strike, QE to the full rise, and QF to the full dip, the lengths of these lines being determined as above. Divide the quadrant ZQE into equal parts by radial lines set out at angles of 10° to each other, such as the lines Q I, Q II . . Q VIII. In an inclined plane dipping at an angle of $i°$, a vertical plane making an angle of $x°$ with the horizontal will cut the inclined plane in a line having a dip of $y°$, such that $\tan y = \sin x \tan i$. Thus the tangent of the inclination of the line Q I $= \sin 10° \tan i$, of the line Q II $= \sin 20° \tan i$, etc. By substituting the values of these angles of dip for i in the formula given above, it is possible to calculate the angles on the rise and dip sides respectively, and in this way the radii of the pillar in the plane of the seam can be determined, as shown in fig. 10, where D is assumed to be 500 ft., i 18°, and b 10°. The shape of the pillar thus obtained is an inconvenient one, and in practice it is best replaced by a rectangle with truncated corners just sufficiently large to include the curved area obtained by the above calculation. For approximations a circle drawn on the line of full dip may be substituted, or spirals increasing regularly from the width of the pillar on the strike to the length of the pillar on the full rise and decreasing in the other direction from the width of the pillar on the strike to the length of the pillar on the full dip.

(See 'Protection Against Damage by Subsidence,' by H. Louis, *Trans. Inst. Min. Surv.*, 1928.

Another method, being practically that of the late Mr. T. A. O'Donahue,* is as follows:—If D be the depth of the seam and T its thickness, in a horizontal seam a pillar of radius R should be set out such that $R = (0{\cdot}19 + 0{\cdot}01\,T)D$, all dimensions being in feet. If the seam is inclined at an angle $d°$ as above, the distance from the vertical through the point to be protected to the edge of the pillar on the rise side should be $R + \frac{2D}{3}\left(\frac{\tan d}{1 + \tan^2 d}\right)$, and on the dip side $R - \frac{D}{3}\left(\frac{\tan d}{1 + \tan^2 d}\right)$. A circular pillar should be set out with radius $R + \frac{D}{6}\left(\frac{\tan d}{1 + \tan^2 d}\right)$, the centre of the circle being at a distance $\frac{D}{2}\left(\frac{\tan d}{1 + \tan^2 d}\right)$ to the rise side of the point S. If a rectangular pillar is preferred, the square circumscribing this circle may be set out. Various other formulas have been proposed, but the two above given appear to be satisfactory.

In practice it is generally an area and not merely a point that has to be protected, the area being usually a circle, a square, or a rectangle. As a general rule this can be done in various ways. If the area is a circle or a square the radii of the pillar can easily be calculated. In other cases a number of suitable points on the periphery of the area (*e.g.*, the corners of a rectangle) should be selected and the protecting pillar for each be determined as above; the irregular figure thus obtained should be enclosed in a figure of some simple form (*e.g.*, a rectangle with truncated corners), re-entering angles being avoided. In cases like this, where the solution of the problem involves so many uncertainties, an approximate result is all that can be obtained, and a liberal margin should be allowed for safety.

Bord and Pillar working.—Pillars may be square but are mostly rectangular, sides varying from 30 to 80 yds.; 30 yds. by 40 yds. to 40 yds. by 60 yds. are usual sizes. Some engineers give areas proportional to depth; for seams 100 to 200 yds. from surface, pillars about 30 by 40 yds.; 200 yds. to 300 yds., 35 by 50 yds.; 300 to 400 yds., 40 by 60 yds.

The Coal Conservation Committee of the Ministry of Reconstruction recommends the following proportions:—

Depth from Surface.	Area of Pillar.
< 100 yds.	300 sq. yds.
100–200 "	500 "
200–300 "	800 "
300–400 "	1100 "
400–500 "	1400 "
500–600 "	1700 "

In *panel working* a rib 30 to 60 yds. wide is left between the districts, the latter being usually 20 to 50 acres in area. In American mines the width of rib is often determined by the expression $T\,(5 + 0{\cdot}01\,D)$, where T is the thickness of the seam and D its depth below surface.

* See 'Subsidence caused by Coal-Mining,' by T. A. O'Donahue, *Trans. Inst. Min. Eng.* vol. lxxviii., 1929, p. 91.

Welsh Stall working.—Single stalls are usually about 12 yds. wide with 12-yd. ribs, double stalls up to 18 yds. wide with 24-yd. ribs between them. In America the following method is sometimes used :—

Width of pillar $W = \frac{T\ D}{100}$, and width of stall $= \frac{D}{W}$, where T is the thickness of seam and D its depth, both in feet.

Subsidences.

(See Second and Final Report of the Royal Commission on Mining Subsidence. Cmd. 2899. 1927. 'Mining Subsidence,' by Hy. Briggs, 1929, also 'Principles of Subsidence' (Lane and Roberts) and 'Subsidence resulting from Mining' (L. E. Young and H. H. Stock), *University of Illinois Bulletin.*)

According to O'Donahue, the working out of a coal seam 4 ft. thick will cause a subsidence of the surface of 3 ft. if the seam be not more than 200 yds. deep, and from 12 to 18 ins. if it be 800 yds. deep. It was shown that at Monkwearmouth, working two seams 6 ft. and 4 ft. thick respectively at depths of 1,725 ft. and 1,600 ft., caused surface subsidences of 6 ft. to 6 ft. 9 ins.

At Dunkirk collieries working two seams 5 ft. and 6 ft. thick, 50 yds. apart, at a depth of 445 yds., caused a subsidence of 6·8 ft. in five years and 8·92 ft. in ten years, after which it ceased.

In Staffordshire working a 5 ft. seam at a depth of 1,626 ft. caused surface subsidences varying from 1·34 to 1·47 ft.: these reached their maximum in about 29 months.

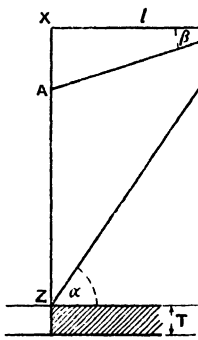

FIG. 3.

In the Doncaster district the surface subsidence may be expected to be about 60 to 70 per cent. of the thickness of the mineral extracted. (Report on Mining and Drainage in an area around the County Borough of Doncaster. Ministry of Agriculture and Fisheries, 1928.)

Final subsidence at the surface is equal to the thickness of the seam actually worked out (*i.e.* the thickness of the seam after allowing for any stowage) less the expansion due to the breaking up of the superincumbent measures. If t is the thickness of the seam and d the depth of the seam, both in feet, and k the coefficient of expansion of the strata, the surface subsidence equals $t - kd$; in ordinary coal measures with seams of moderate thickness and at moderate depths k appears to be of the order of 0·2 per cent., so that if D is the depth of the superincumbent strata in hundreds of feet, then the subsidence equals $t - 0{\cdot}2$ D feet. The coefficient appears to increase with increasing thickness of the seam, which gives the strata more room to break, and it decreases as depth increases, probably because the weight of the overlying strata re-compresses to some extent the strata expanded by fracture, and this effect appears to be sufficiently well marked to prevent $t - kd$ ever coming down to zero, though it is not impossible that it might do so in the case of narrow seams at very great depth.

There are too few data available to give numerical expressions for the above general statements.

Besides the vertical subsidence over the worked-out area, a zone of draw exists over the solid coal, the breadth of which = depth of seam × tan angle of draw as given above. Let XY, fig. 3, represent the zone of draw.

Under normal conditions as to character of superincumbent strata, dip of strata, thickness of seam and absence of faults in the neighbourhood, mining engineers usually reckon on a maximum extension of draw, measured on the surface, equal to one-third of the depth from the surface of the excavation.

Let S (= XA) be full vertical subsidence; l (= XY) be length of draw (width of zone of draw); H = depth of seam; T = thickness of seam; α° = angle of draw measured to the horizontal, said to be about 70° in coal measures; β° = angle of inclination of drawn surface.

There is a horizontal displacement from Y to X, and this is a maximum in the middle of the zone of draw, becoming zero at X and Y.

Tan $\beta = \frac{S}{l}$ l = H cot α. For seams 4ft. to 10 ft. thick, S = (0·5 to 1·0) T, when unstowed, (0·25 to 0·5) T, when hand-stowed. Maximum horizontal displacement varies from 0·05 to 0·3 T and $= \frac{Sl}{4H} = \frac{S \cot \alpha}{4}$.

(*A. H. Goldreich*, '*Die Bodenbewegungen im Kohlenrevier und deren Einfluss auf die Tagesoberfläche.*' 1926.)

In the Zwickau (Saxony) district seams dipping 15°, aggregating 28 ft., worked at depths from 2,000 ft. to 3,000 ft., cause subsidence of 70 per cent. of thickness worked by goafing, 40 per cent. by hand-stowage, 10 to 5 per cent., averaging 7 per cent., by hydraulic stowage. The angle of draw by the two former methods is 80°, flatter by last-named method. In mining under densely built-over areas hydraulic stowage gives better protection against damage than leaving safety pillars. (*Goldreich, op. cit.*)

Coal Getting Machines.

In hand kirving, the average height of a kirving is 13½ ins. in front and 1⅜ in. at back, by a depth of 3 ft., giving a volume of 1·9 cub. ft. of coal kirved out per linear foot of coal face (equal to 16 per cent. on a 4 ft. seam). In a 6-hour shift a hewer in ordinary coal will kirve a bord 5 yds. wide to a depth of 1 yd. or about 7½ sq. ft. per hour of shift. A man will kirve about 9 sq. ft. per hour's actual hewing time after the jud has been nicked in a bord; in a wall he can kirve about three-quarters as much as in a bord, and in longwall work he can kirve one and a-half times as much as in average narrow work. Allowing for his other work a hewer in Northumberland and Durham averages about 38 sq. ft. of kirving per shift.

Machine cutting in those cases where the conditions are favourable to its application gives up to about 65 per cent. more output per man employed; on the average about 10 per cent. more round coal is made by machine than by hand, and a greater output of coal can be obtained from a given seam. Where a mechanical coal cutter can be worked with a face conveyor the ideal is reached in respect of the use of both. The other conditions making for economic application of mechanical cutters are:

(*a*) where the seam is not abnormally thick;
(*b*) where the coal will stand to be cut;
(*c*) where the seam contains a soft floor or a band of soft dirt in which the cut can be made;
(*d*) a good roof;
(*e*) a flat or moderately inclined seam;
(*f*) where a large output is a desideratum and can be profitably disposed of.

Coal-cutting machines for longwall work are chain-cutters; disc-cutters and bar-cutters have gone out of use. Machines may be air-driven, using compressed air at 35 to 65 lbs. per sq. in. at the machine, or electrically-driven (direct, alternating, or tri-phase) at voltages of 250 to 450. The power consumption varies between wide limits, between 12 and 30 h.p. Compressed air coal-cutters cost 250*l.* to 300*l.*, electrically-driven coal-cutters 350*l.* to 450*l.*; a complete plant for a pit using 10 machines would cost about 10,000*l.* with the former and 11,000*l.* with the latter form. The area undercut per hour varies from 45 to 140 sq. ft., 90 sq. ft. being about an average, per hour of working time. An average shift's work may be taken as about 500 sq. ft. Air consumption 1,000 to 3,000 cub. ft. free air per sq. yd. undercut.

In Great Britain, in the year 1943, there were 7,794 coal-cutting machines at work which cut 134,131, 691 tons of coal or 69 per cent. of the total output, as against (year 1941) 89 per cent. of the output of bituminous coal in U.S.A.

According to Mr. Mavor (*Trans. Inst. Min. Eng.*, vol. l., p. 641) a good compressor will compress 6 cub. ft. free air per minute to 60 lbs. per sq. in. per b.h.p. Tests showed coal cutters to use 143 to 1,146 cub. ft. free air per minute, or 620 to 3,642 cub. ft. per sq. yd., at mean pressure of 23 lbs. per sq. in. at machine and 68 lbs. at compressor.

COST.

Mr. Mavor gives average costs as follows:—

	Per shift. s.	d.	Per ton. d.
Interest 5 per cent. on 450*l.*	1	9	0·21
Depreciation 12½ per cent.	4	4	0·52
Labour	33	0	4 00
Air power	23	0	2·77
Picks, oil, etc.	8	4	1·00
Repairs	12	10	1·50
Total	83	3	10·00

In narrow work percussive coal-cutters are used, also chain-heading machines and arc wall machines. Percussive cutters supported on a fixed column are also used; they work with compressed air at 50 to 70 lbs. per sq. in., the air consumption being 100 to 300 cu. ft. of compressed air per sq. yd. undercut; different makes run at 300 to 600 blows per minute. A machine has undercut 30 sq. ft. per hour, but their usual performance is 80 to 100 sq. ft. per shift. Percussive cutters of the Ingersoll type on wheels are also used; these machines weigh 5 to 7½ cwts.; they use air at 70 to 90 lbs. pressure per sq. in., with an average consumption of 100 cu. ft. of free air per min., and strike about 150 blows per min.; they will undercut 15 to 50 sq. ft. per hour of running time, or 50 to 200 sq. ft. per shift.

The use of pneumatic picks both for getting coal and for making height in roadways has become a recognised feature of coal mining, especially in continental collieries. In the year 1938 nearly 13,000 such picks were in application in Great Britain for cutting coal or ripping. These picks are usually from about 17 to 27 lb. in weight, the consumption of air—according to size and weight—varying from 24 to 32 cub. ft. per minute. (A percussive hammer drill consumes at least 33½ cub. ft., whilst a light rotary drilling machine will consume probably 43 cub. ft.)

Chain heading machines may be driven electrically or by compressed air, using 10 to 20 h.p.; these machines can undercut about 50 sq. ft. per hour, but it is rare that 200 sq. ft. can be kirved per shift. See 'The Driving of Narrow Places,' by S. Walton-Brown (*Trans. Inst. Min. Eng.*, vol. lxxiii, 1927, p. 506).

Arcwall machines will cut 10 to 15 places per shift in roads 4 to 5 ft. wide, the usual depth of undercut being about 6 ft.; these machines weigh about 3½ tons, and their motors develop about 40 h.p.

Arc wall coal cutters as used in bord and pillar work are required to flit from place to place 10 to 15 times during a shift. They are mounted on rail-wheels, pneumatic tyres, or caterpillar tracks, and are electrically-driven. One cutting jib and gearhead is used for making vertical cuts and horizontal cuts at any horizon within the range specified, up to about 7 ft. Adjustment of height of cut is made by power-driven screw-jacks, or by hydraulic jacks. The usual depth of cut is 6 ft. Machines of this type weigh about 3·5 tons and are driven by a single motor of about 40 h.p. with clutch engagements to the various motions.

The Stanley header cuts roads circular in cross-section through coal, using 15 to 40 i.h.p. A road 5½ ft. in diameter can be driven through coal at the rate of 10 ft. per 8-hour shift, or six times as fast as handwork, the cost being sometimes rather less, sometimes rather more than hand labour, namely 2*s*. 6*d*. to 4*s*. per foot of advance, everything included, as against 2*s*. 8*d*. by hand.

The Jeffrey Entry driver cuts, breaks down, and loads the coal into tubs.

In the U.S.A. Longwall machines with jibs 40 ft. long cut and load 350 tons per shift. A machine with a 50 ft. jib is worked by five men, and in a 6 ft. seam with a strong sandstone roof cuts and loads 200 tons per shift or 400 tons per day; a machine with a 200 ft. jib, to cut and load 1,000 tons per shift is being built.

Increased mechanisation of coal getting in this country during the 1930's was accelerated by the introduction of American types of machines, especially loaders, during World War II. The N.C.B. aims to develop and apply such methods to the full. The American types of loaders applicable in our conditions are mostly for pillar and stall working, *e.g.* Joy loader, and Duck-bill loader. But it is thought that longwall machines must be developed to suit British conditions, and much has been done to that end.

Much the most successful at present is the A. B. Meco-Moore Cutter Loader. This machine is a development of the common chain coal-cutter; in fact it was originally conceived as two separate units, the loader to follow after the cutter unit. The first model was tried out in 1934, but not until 1941, under stress of war conditions, was intensive development undertaken which led to the trial in 1943 of the prototype of the machines now in use.

The cutter unit of the High Type machine is an ordinary 50 h.p. A. B. coal-cutter fitted with an extra chain jib driven through a gear train, and set to cut at about mid-height of the seam or higher, and immediately above the bottom jib; the latter is 6½ ft. long and makes a 7-in. kerf, and the upper jib is 5½ ft. long and makes a 5-in. kerf. Both jibs can be swung round to cut on either side of the machine, and the chains run and cut in opposite directions.

The loader unit is about the same size as the cutter unit and is attached to its rear end by a hinged coupling. This unit also helps in cutting, by means of a shear jib of triangular shape mounted in the vertical plain in line with the end of the shorter horizontal jib. The sheat jib makes a 5-in. kerf extending from roof to floor, which forms the new face of the longwall. This jib is pivotally mounted so that it can cut when the loader moves in either direction.

The loader elements of the loader unit comprise a short transverse conveyor, a riffle bar, and two gummers. The conveyor is of rubber armed with steel slats and side chains to give a positive drive. It is about 5 ft. long and set some 9 in. above floor level; it feeds the coal on to a normal face conveyor, usually of the bottom-belt type. The rotary riffle bar is mounted horizontally and immediately in front of the conveyor. It carries picks arranged on two helices which in turning break up the coal and lift it on to the conveyor. The gummers are of the screw or fan type and their function is to remove fines. The loader unit has one 50-h.p. motor with shaft drives to shear jib chain and conveyor, etc. Each motor has a separate trailing cable and controls.

In favourable conditions, *e.g.* seam fairly level (the limiting dip of face is about 1 in 4), coal amenable and cleat angle satisfactory, the cut coal collapses on to the conveyor under the action of the riffle bar. Under less favourable conditions in respect of coal or roof for example, overcutting and prior bursting or firing of the coal may be necessary. The *Low Type Meco-Moore Loader* is a facsimile of the High Type built low enough to work in a seam slightly more than 3 ft. thick. Although fitted with two horizontal jibs, the intention is not to use the top jib normally. This machine is 16 ft. 9 in. long by 3 ft. 1 in. wide by 2 ft. 0 in. high, or 2 ft. 7 in. with top jib, and weighs 10 tons. It is driven by two A.C. motors of 60 h.p. each, and takes a cut of 4 ft. 6 in., 5 ft. 0 in. or 5 ft. 6 in. at choice. Experience with the Meco-Moore machines is given in papers by Forrest Anderson, B.Sc.,* and by Messrs. Young and Sansom.†

The Meco-Moore Loader will cut in both directions along the face. But in order to do so it has to be partly dismantled and re-erected at each end of the face, in order to bring the jibs, etc., into correct relative positions again.

The operations involved in reassembling the machine at each end of a face requires considerable pit room. The preparation of these end places or stables is done by hand with ordinary coal cutters and the work often represents a considerable addition to the labour required to operate the cutter-loader itself. For example, a face 140 yds. long may comprise 20 yds. of stables. It is also considered a drawback of the Meco-Moore machine that such a high percentage of the coal got is reduced to gummings by the chain picks. A strong body of opinion holds that a machine using a wedging action would prove more satisfactory for getting and loading on longwall faces in British coals generally, and much thought and development work has been done to that end in recent years.

The Mavor & Coulson slabbing machine, now under development, is more akin to the German Coal Plough in that it shears the coal off the face by a wedging action, without a chain-type of cutter. It is in fact a plough type of machine designed to suit our coal, which is harder than German coal. This machine is hydraulically operated with electric power supply, and is self-propelling. It works on a buttock 2 ft. to 3 ft. wide, and shears the coal off the face by means of multiple wedges which are thrust forward, the machine itself being anchored meanwhile by a powerful vertical jack set between roof and floor. The whole thickness of seam is broken down by this means, and thrust over on to a normal face conveyor.

One Coal-Plough, as developed in Germany during the war, has been working in a suitable seam of soft coal in Durham for about two years, with fairly satisfactory results. This machine shears out the lower part of the seam, to a height of about 18 in. and is hauled to and fro by means of a rope and winches, taking an 8-in. or 12-in. cut each way. A specially constructed scraper conveyor is required, to serve the secondary function of holding the plough up to the face.

Another machine, not unlike the Meco-Moore in principle, has been developed by Messrs. Eickhoff of Bochum. It has two superimposed horizontal jibs ; but the lower one is bent upwards at the end of the horizontal portion, thus forming a vertical shear jib extending to the height of the upper jib. The machine travels on top of a shallow scraper-chain conveyor, and the coal, as it collapses is directed into the conveyor by a series of paddles. Several inches of floor coal left below the bottom jib have to be got up by hand.

In pillar and stall work the common method of mechanisation is to break the coal down first in the usual way with the aid of coal-cutters, and to load with separate machines, often of American make or design. Of these the Duckbill Loader and the Joy Loader are most widely used. Either type may load directly on to a conveyor, or into shuttle cars for transport to a central loading point. Both loaders nose their way into the broken coal at floor level, and the coal is gathered and drawn up on to a conveyor by means of gathering arms or by an oscillating action. The Samson Loader, made by Messrs. Mavor & Coulson is 2 ft. high and 4 ft. 10 in. wide, with gathering arms which sweep 5 ft. 2 in. wide. It is driven by one 30 h.p. motor and moves on crawler treads, and can load up to 4 tons per minute of coal or stone. The Distington Engineering Co., make a duck-bill loader-cum-shaker conveyor.

Air-driven mechanical shovels similar to a surface excavator are coming into use, chiefly for stone-work in headings. The Joy-Sullivan type, which is made in Great Britain, can load from 2 to 3 tons per hour. It is mounted in a four-wheeled truck about the size of a tub, and the bucket swings back over the truck to load the tub standing behind it. Similar shovels are made by the Consolidated Pneumatic Tool Co., and by Messrs. Eimco.

Conveyors have been extensively used for bringing the coal to the gateways and, more recently, along the gateways also. There are four main types : (1) troughs containing scraper-chains, either endless or reciprocating, (2) endless belts, (3) shallow trucks or trays hauled by ropes, (4) shaker conveyors, (5) scraper conveyors, hauled by various machines. The Blackett conveyor is an example of the first type ; the chain is 6-in. pitch and rests in a trough 12 ins. wide at the bottom, 18 ins. at the top, 9 ins. deep, made in 6-ft. lengths ; it will carry up to 30 tons per hour along faces 100 yds. in length. Most of the other forms have lower capacities, and are suited to smaller outputs or shorter faces. In 1943 there were 9,496 conveyors in use at British collieries carrying 66 per cent. of the total output as against (year 1938) 25·8 per cent. in U.S.A.

† *Third Report of Fuel Economy Committee, Brit. Assoc.*, 1920.
‡ Royal Commission on Coal Industry (1925).
‖ From the Annual Statistical Summary for the year ended December 31, 1938, issued by the Department of Mines. These summaries ceased to be issued during the War period, but were resumed in 1945.
‡‡ The Coal Industry being under a system of Government semi-control.

The Support of Workings.

Supports of various kinds are used to achieve one or more of these objects given in order :—

(a) To maintain ways and working room in a condition and large enough for their purpose.
(b) To prevent falls of ground, both as a source of injury to personnel and of obstruction to movement.
(c) To control the closure of the strata subsequent to mining, and to utilise their energy as far as possible in the extraction of the mineral.
(d) To reduce in amount and to mitigate the effects of surface subsidence.

Although (a) and (b) are quite distinct functions they are often fulfilled at once by the same supports. A typical instance is that of steel arches as used to maintain some 5,000 miles of roads in British collieries. Their strength is infinitesimal compared with the weight of cover at, say, 4,000 ft., yet they provide resistance sufficient to support the surrounding annulus of rock and maintain the road in a safe condition and of size adequate for its purpose. Steel arches have proved the best solution yet found for this most difficult problem, largely because they combine strength with flexibility and capacity to offer continuous resistance. In metalliferous mines the roads are more often made in strong rock, which may not be disturbed by other mining operations. In such cases a concrete lining may be used for safety (a) and to reduce air resistance (b), at depths as great as 6,000 ft. or 8,000 ft.

With regard to (c) a good instance is in the method of longwall working of coal as practised in this country and on the Continent. The face supports serve the functions (a) and (b) and prevent the premature collapse of the beds immediately overlying the seam. The packs or other permanent supports, starting some 12 to 15 ft. or more from the face, slowly acquire the full weight of the overlying beds. Both the face and permanent supports yield as the face advances, usually to between 50 and 80 per cent. of the seam thickness at 100 yds. from the face. Hence the coal face is subjected to vertical loading, as it were by a huge lever. Subject to consideration of the strength of roof and floor and of the coal itself, the method of support can be adjusted to suit the system of getting and the type of machines used for that operation.

Permanent supports, distinct from mineral left *in situ* to protect the surface or shaft, etc., are usually built of mine waste and the like in collieries, with or without some stiffening or reinforcement. In metalliferous work filled or empty timber cogs or mats are used. In this country packing is almost entirely done by hand, in the form of strips advancing with the face and filling upwards of 50 per cent. of the waste. Attempts to mechanise this bulk movement of material are in progress, using German type of equipment.

Stowing by Machine.

Experience with methods of packing or stowing (other than by hand) is more extensive on the Continent than in Great Britain ; in Germany this was in part due to more severe regulations in respect of surface subsidence. The methods tried include hydraulic, pneumatic and mechanical stowage. In the former, the water proved troublesome, and this method has now only limited use, chiefly in Silesia. In the Ruhr 130 pneumatic stowing plants were in use at 52 collieries in 1944.

The choice of method is influenced by mining conditions, in particular by the packing material available and the percentage of stowing required. Solid stowing is possible by the pneumatic method, thus limiting subsidence to about 50 per cent. of the initial height of pack, as compared with 60 per cent. for solid hand packing.

In a typical pneumatic stowing machine as used at Bulcroft Colliery* mine waste from various parts of the pit is passed through a crusher and then dedusted, damped and fed to the blower which causes it to be conveyed along the pipe line and ejected through a nozzle into the pack. The nozzle is directed by one or two men, and shuttering or brattice is attached to props to control the size of pack.

The driving air is obtained from the compressed air mains. A pressure of 30 to 50 lb. per sq. in. is required, depending on the nature of the material. The velocity of the air stream increases between inlet and exit from about 125 to 400 ft. per second. The stowing material lags behind the air velocity by about 30 to 100 ft. per second depending on its size and nature ; some is air-borne, some rubs or rolls along the pipes. In most cases cast-iron pipes of 6 ins. to 8 ins. diameter are used, with quick-clip joints ; the elbows may have to be protected by internal wearing pads of stone or other hard substance, if the material is abrasive. Depending on size of pipe and its length and type of material, air consumption lies usually between 2,000 and 5,000 cub. ft. per cub. yd. of stowing. Delivery up to 300 yds. is normal, and 600 yds. is practicable.

Material up to 3 or 4 ins. can be conveyed, but smaller maximum sizes and a fair grading gives the best results. Up to 2,500 cub. ft. per hour can be stowed with suitable material, but only half that amount with a sticking or clogging type of material. The total cost of pneumatic stowing is about 6*d*. to 1*s*. 6*d*. per ton of coal mined, chiefly due to wages, air, repairs and maintenance of plant.

* 'Pneumatic Stowing at Bulcroft Main Colliery,' by J. Hunter. *Trans. Inst. Min. Eng.*, vol. cv., Pt. 3, 1945.

An alternative method of stowing is wholly mechanical. Suitably crushed material is fed on to a high-speed belt in such a way that it acquires a comparable speed before being flung out of the machine in the direction required. Wet or dry material up to 3-in. size can be cast 30 ft. by machines now under development.

The advantages of stowing by machine are denser packs with less labour and total cost. The greater density has proved highly beneficial in reducing air leakage and the incidence of spontaneous combustion. In so far as mechanisation facilitates solid stowing it reduces the amount and ill-effects of surface subsidence.

The resistance developed by hand-built packs has been investigated with mechanically-operated dynamometers let into the middle of a piece of floor before that part of the pack was built. In general the curve of load plotted against face advance increased slowly at first, and then more rapidly until it reached a peak value. This occurred at 50 to 60 yds. from the face in seams at shallow depths, 200–300 ft. and at 70 to 80 yds. in seams at moderate depths, 1,000 to 2,000 ft. A considerable fall in load then occurred, followed by a further increase until a steady load was reached, usually somewhat less than the first peak value. The final stable loads measured on strip packs occupying about 50 to 60 per cent. of the waste were usually 1·5 to 3 times greater than those estimated for the depth of cover acting on the unmined seam.

Compression at the centre of the pack started at a high rate, but it was much reduced when the load reached peak value, and subsequently reached a stable value between 30 and 40 per cent.*

Stowing by means of filled bags made of jute or wire-netting is used extensively at some British collieries, chiefly for building the gate-side pack-walls when large stones are lacking, and in conjunction with pneumatic stowing. The bags are sent in filled with washery waste, or they are filled on site by hand, using a simple frame to hold the bag in position. Used in gate-side walls the bags have the advantage that steel arches can be erected on the walls in such a way that the initial subsidence of the road can be accommodated without damage to the arches.†

TIMBER PROPS.

The strength of timber props depends largely on the species of timber and its condition of seasoning, *i.e.* moisture content; crookedness and decay can weaken them incalculably, and knots are deleterious. As for all struts, the slenderness ratio (length over radius of gyration, or 4L/D for round props) is also a critical factor. The strength of props with slenderness ratios of 10 or more (*i.e.* L = 2·5D) is less than that of short specimens in which L = 2D. Compression tests on such short specimens of clear timber provide the basic strength figure f_c, or fibre crushing stress, as given below for some typical softwoods and hardwoods.‡

Species.	f_c, lb. per sq. in.	$f_c \times 75$ per cent.
SOFTWOODS.		
Larch, European	3,500	2,600
„ Japanese	2,800	2,100
Fir, Douglas	3,300	2,500
„ Silver	3,000	2,250
Pine, Corsican	2,700	2,100
„ Scots	3,000	2,250
Spruce, European	2,600	2,000
„ Sitka	2,300	1,700
HARDWOODS.		
Ash	3,900	3,000
Beech	3,700	2,800
Oak	3,800	2,850
Chestnut (Sweet)	3,400	2,500

These values of f_c are for unseasoned timber, *i.e.* having a moisture content exceeding 30 per cent. of the dry weight of wood. Air-dry timber, seasoned to a moisture content of 12 per cent., is about twice as strong, *i.e.* of the order of 5,000 to 7,000 lb. per sq. in. for softwoods and 7,000 to 8,000 lb. per sq. in. for hardwoods.

For good average quality props of the usual slenderness ratios the maximum stress f developed is considerably less than the fibre crushing strength. This loss is due to the effects of slenderness, bow, and knots. The maximum prop stress f varies from 60 to 80 per cent. of the fibre crushing stress f_c for props of 60 to 40 slenderness ratios. For average props of 48 slenderness ratio, *i.e.* L = 12D, the value of f may be taken as 75 per cent. of f_c.

In the result a useful approximation for the strength of unseasoned softwood props is 1 ton per sq. in. of area; and for unseasoned hardwood props, 1·25 tons per sq. in.

Experience in testing large consignments of timber props shows that in any one group of 20 or more similar props an overall variation in strength of 2 to 1 may occur ; *i.e.* from 70 per cent. up to 140 per cent. of the mean strength.

The strength of timber in compression across the grain, as used in cogs, chocks and cribs, etc., depends on the species of timber and its condition, on the initial areas of contact between adjacent pieces and on the amount of compression or yield sustained.

Chocks.

Chocks built of sawn softwood 4 ins. to 6 ins. square will carry loads producing stresses of 300 to 450 lb. per sq. in. of contact area when compressed about 3 per cent. The stress increases to a maximum of 600 to 800 lb. per sq. in. at about 20 per cent. compression. For chocks built of sawn hardwood the corresponding stresses at 3 per cent. and 20 per cent. yield are of the order of 800 to 1,000 and 1,500 to 1,750 lb. per sq. in. respectively. Steel chocks are now widely used.

Cogs.

Cogs built of round softwood 6 ins. to 8 ins. in dia. two sticks to each layer and 6 ft. square have a linear load-yield curve, reaching 40 tons at 20 per cent. and 60 tons at 30 per cent. yield. Similar cogs filled with mine rock also have a linear load-yield curve but are immensely stronger. Depending on the strength of the rock and care in building loads of 200 to 400 tons are sustained when the yield is 20 per cent.

Steel Props.

Steel props are much more reliable than timber props ; they are usually of H sections which are often specially rolled with broad flanges and thick webs. A usual ratio of length in feet to width in inches is 1·5 to 1, as compared with unity for timber props. Eccentric loading is much reduced by folding the flanges to close and round the ends of the props, by the use of timber lids, and the relatively softer floor. Depending on the quality of steel, *i.e.* whether of 30, 40 or 50 tons approximate ultimate tensile strength, a prop will carry a maximum load of about 17, 21, 24 tons per sq. in. or about 5, 6·2, or 7 tons per lb. weight per ft. of section. After maximum load a steel prop will buckle but still carry about half its maximum load when the centre deflection is equal to the width of section.

Special Steel Props.

Several types of mechanically-operated steel props are used successfully under particular conditions, both in this country and abroad. One type is merely a screw-jack which is convenient as a temporary support in conjunction with power loaders. On the continent props capable of adjustment in height, tightening in position, yield under a suitable load, and release, depend usually on frictional resistance between telescoping parts. High transverse forces are required to provide suitable resistance, and this implies a strong wedge box and a heavy prop. The G.H.H. is a prop of this type used with the German coal plough, and it weighs 25 lb. per ft. for a prop 3 ft. long. In this country the most successful mechanical props are not adjustable or yielding ; they merely have capacity for tight setting, with or without means of quick release from a safe position. Of the former class the Bathgate prop is typical ; it comprises a suitable length of H steel section with a cast steel head which is raised or lowered about 1 in. by means of a transverse wedge, also of cast steel. The Sylvester prop is similar, but has the additional feature that on drawing a catch the head collapses and the prop is ejected.

Dowty Hydraulic Props.

An important recent introduction is the hydraulic prop, which after some three years' intensive development by Dowty Mining Equipment, Ltd., is being used in extensive trials in the East Midlands. It appears to have more than fulfilled the economies anticipated in reduced costs for material and labour underground, and its use is likely to become widespread. The prop comprises two steel tubes filled with oil, the lower one forming the working cylinder. It is extended by forcing oil out of the upper tube (or ram) into the cylinder by means of a pump built into the ram. The pump is operated by a detachable handle engaging a crankshaft carried in a housing in the side of the ram. Thus the prop can be extended 2 or 3 ft. if required, and a tight setting obtained.

At a predetermined load of about 20 tons the prop yields by passing oil from the cylinder back to the upper tube. This is done via an internal pipe connecting the piston head of the ram to a spring-loaded control valve set in a housing near the top of the prop. This same valve can be pulled off its seat by hand (using a cable or rod hooked to a shackle in the valve housing) in order to release the load on the prop, which can then be withdrawn. The prop weighs about 13 lb. per ft. and may be had in practically any length. The present price is £10 for props of normal length, but this may be reduced to £7 10*s*. when manufacture on a suitably large scale can be begun.

The economies effected by the Dowty hydraulic prop are due to the saving in time in setting and withdrawing operations, and economy in supplying lids and new props, and in restraightening bars. The improved roof control and increased safety are likely to yield equally satisfactory returns.

Steel Arches.

The specification for ' steel arches for use in mines ' given in B.S.S. 227 (1934) is now outdated in several respects. Considerable quantities of arches are now made in steel of about 40 tons

ultimate tensile strength, in addition to those of 30 tons and 50 tons specified. Also many new sections have been introduced, some of them designed for this specific purpose; and of the three shapes of arch specified, the horse-shoe shape proved inferior and is not now in use.

The supporting value of a steel arch depends on the strength of the section, on the efficiency of the strutting between arches, and on the size of road and mode of incidence of the ground pressure. The strength of the section varies with the weight per ft., the overall dimensions, and on the quality of the steel.

The actual strengths of 8 ft. diameter straight-legged arches when subjected to load fairly well distributed over the crown, and with the sides firmly supported, varies greatly for the reasons given above. Arches of 50 tons tensile steel and 4 ins. by 2·5 ins. by 2 ins. section weighing 11 lb. per ft. and erected with mediocre strutting carried 27 tons per arch maximum load, equivalent to about 3·3 tons per ft. diameter of arch or 1 ton per sq. ft. of roof area with arches set at 3 ft. crs. The strength of arches of this section was increased 2·6 times, to 70 tons, when the arches were well strutted, as by a continuous brick lining 3 ins. thick, built between the flanges, or by steel struts and corrugated sheet lagging. Arches of 5 ins. by 4½ ins. section 18 lb. per ft. wt. and rolled in 30 tons steel set with mediocre strutting carried 56 tons per arch, and 108 tons or nearly twice as much when well supported by continuous brickwork lining 4½ ins. thick. In this case the increase in strength given by good strutting was not so large as in the case of arches of the slimmer section.

The actual strengths are perhaps of less interest than relative strengths in terms of the intensity of ground pressure resisted. This probably varies inversely as D^2, D being the diameter or width in feet; if p is the ground pressure, then the relative strengths are as follows:—

$D =$	8	10	12	14	16	18	20
$p =$	100	66	44	33	25	20	16

Under normal conditions on roads 14 ft. wide well-lined arches of 5 ins. by 4½ ins. section and of mild steel should carry up to 36 tons per arch, which is equivalent to the dead weight of 12 ft. of rock, on arches set at 3 ft. crs. Under similar conditions arches of 4-in. by 2-in. by 2½-in. section in high-tensile steel should carry 8 ft. of cover.

These figures for actual depth of ground or strata supported may appear slight, but they are of the same order for face supports.* As pointed out above, in relation to the weight or thickness of superincumbent strata the strength of most supports is negligible in itself. But by judicious application they can provide that stabilising influence which enables the fractured strata to cohere sufficiently to prevent collapse. In the case of steel arches the annulus of ground around the road which they control may be well able to support both itself and the weight of higher beds as well. Not infrequently the strength of the floor of the road proves the limiting factor.

Colliery Consumption.

According to the Coal Conservation Committee of the Ministry of Reconstruction, 1918, colliery consumption in Britain varies from 5 to 9·43 per cent., averaging 6·8 per cent., of which 6·2 per cent. is produced by the direct combustion of coal under boilers, and the balance from outside sources. In 1923 colliery consumption amounted to 6·11 per cent. and miners' coal to 2·34 per cent. of the output, and in 1924 to 6·21 per cent. and 2·46 per cent. respectively. The average colliery consumption at British collieries at the present time (1947) is estimated to be 6 per cent. At a modern colliery at which not much water is made the colliery consumption should not exceed 3 per cent. of the output.

Mining in Veins and Masses.

Methods employed in veins are:

- Underhand stoping.
- Overhand stoping.
- Combined underhand and overhand stoping.
- Rill stoping.
- Shrinkage stoping or magazine mining.

Irregular deposits, wide veins, thick and steeply inclined seams may be worked by the following methods:—

- Lost pillars.
- Vertical slices.
- Horizontal slices taken transversely.
- Horizontal slices taken longitudinally.
- Top slicing.
- Caving.
- Magazine mining.
- Square set timbering.

Of these, overhand stoping is the most general, underhand stoping being only used in quite special cases, as when there is only a small quantity of payground to be taken below a given level. Overhand stoping can be used for veins of medium width, say up to 10 ft. on the average.

* See 'The Strength of Undermined Strata,' by W. H. Evans, Ph.D., A.M.I.Mech.E. *Trans. Inst. Min. and Met.*, *Vol. L.* 1940–41.

Rill stoping is mainly employed in Western Australia. Magazine mining suits veins of any width, provided that they are not too flat, that the walls are fairly good, and that the whole of the veinstuff has to be extracted. Slicing and caving are used in wide veins and irregular masses when the value of the mineral is not great and where cheap methods of working are essential; it is largely used in the hæmatite mines of Cumberland and Lancashire. Square sets can only be used where the mineral is valuable and where large timber is abundant and cheap.

The following classification has been drawn up by the Committee on Mining Methods of the *Amer. Inst. Min. Met. Engs.*, vol. lxxii. 1925.

- **Open cut with or without stripping**
  - Benches
  - Glory holes and milling
  - Placer mining
    - Hand sluicing
    - Dredging
    - Hydraulicing
- **Underground methods**
  - Breast stoping (tabular flat-dipping deposits or beds)
    - Continuous horizon
    - Casual pillars
    - Room-and-pillar
  - Underhand stoping (veins and large masses)
    - Glory hole and milling
    - Open stope
      - With pillars
      - With stalls
      - With square set timbering
  - Overhand stoping (steep-dipping veins or masses)
    - Open stope
      - With pillars
      - With stalls
      - With square set timbering
    - Filled stope
      - Horizontal cut and fill (flat-back)
      - Inclined cut and fill (rill)
      - Square set timbering
      - Piercing or stripping
    - Shrinkage stope
    - Sub-level stopes
  - Top slicing (wide veins or masses)
    - Continuous horizon
    - Panel slicing
    - Block slicing
    - Inclined slicing
  - Caving (large masses)
    - Sub-level caving
    - Block caving
      - Undercut from main level
      - Undercut from sub-levels
      - Back caving into chutes
      - With branch raises
- **Combined methods (large masses)**
  - Alternate shrinkage stope. and pillar
  - Pillars mined by: top slicing, sub-level caving, or block caving
  - Square set timbering: pillars mined by slicing

(See 'The Working of Unstratified Mineral Deposits' by G. J. Young, 1927.)

The costs of stoping vary within very wide limits, and may be illustrated by typical examples.

In Western Australia, with the contract system in force, a miner breaks 7·31 tons of ore per shift. Formerly a miner on day's pay broke only 4 tons per shift.

In eleven of the West Australian mines treating from 9,000 to 22,000 tons of ore per month with veins varying from 4–20 ft. to 6–60 ft. in width the stoping costs per ton of ore range from *6s. 4d.* to *9s.*, averaging *7s.* This includes breaking ore, filling stopes, trucking, hoisting, etc.

On the Rand it costs from 3*s*. 6*d*. to 5*s*. 6*d*. to stope a ton of milling ore in stopes 40 to 60 inches in height. To these figures must be added cost of compressed air, rock drill maintenance, steel sharpening, and administration underground. The first three factors amount roughly to about 1*s*. per ton, while the last would not exceed 1*d*. In some Rand mines one man can break 12 tons per shift per machine, and uses one case (50 lbs.) of blasting gelatine to break 3·5 fathoms of ground. At other mines only 7 tons are broken per man and one case of explosives is used to break 2·5 fathoms.

In Nevada at the Silver Peak Mines each miner breaks 8·6 tons of rock per shift. The total stoping cost is 5*s*. per ton. Miners here receive 16*s*. per shift.

At the Braden Copper Mines native miners break 12 tons of ore per man per day with rock drills in moderately hard rock. The total cost per ton of ore broken, including superintendence and general charges, is given as 1*s*. 9*d*.

In Utah in quartzite with a stoping width of 10 ft., square set system, small air drills, the stoping cost per ton varies from 6*s*. to 8*s*.

At Douglas Island, Alaska, the ore is a mineralised igneous rock of fair hardness, the workable portions of which vary upwards from 30 ft. in width. Wages 12*s*. Machine used 3¼ inches piston diameter. The following figures are taken over a year's working :—

COST OF BREAKING GROUND AT DOUGLAS ISLAND, ALASKA.

General Details.	Ready Bullion.	700 Ft.	Mexican.	Treadwell.
Average number of drills used	10·12	11·586	14·917	39·13
Tons ore broken	151,460	238,696	232,875	830,551
Tons waste broken	2,756	—	10,509	1,670
Tons broken, total	154,216	238,696	243,384	832,221
Total footage drilled	241,679	269,990	362,519	803,542
Tons ground broken per machine per shift:				
Stoping	47·36	42·998	41·26	—
Developing	8·65	11·323	6·58	—
Cutting out	14·30	7·334	10·34	—
Average	23·06	30·41	24·19	28·47
Footage drilled per machine per shift:				
Stoping	29·39	33·587	33·50	—
Developing	39·14	37·78	39·71	—
Cutting out	40·11	33·954	34·79	—
Average	36·12	34·37	35·7	29·41
Tons broken per foot of hole drilled:				
Stoping	1·61	1·28	1·23	—
Developing	0·22	0·19	0·165	—
Cutting out	0·31	0·33	0·30	—
Average	0·64	0·88	0·669	0·96
Costs of breaking ground per shift per machine:	£ *s*. *d*.	£ *s*. *d*.	£ *s*. *d*.	£ *s*. *d*.
Labour	1 14 0	1 8 0	1 10 0	1 9 0
Explosives	9 8	11 4	12 2	11 4
Supplies and power	1 0 0	18 2	1 0 0	1 0 0
Total	3 3 8	2 17 6	3 2 2	3 0 4
Cost per foot of hole drilled	1 10	1 8	1 9	2 0
Cost per ton of ground broken	2 10	11	2 8	2 1
Total cost of mining, including development	4 0	4 9	4 10	4 6
Percentage of total mining cost	2 9	8	2 2	1 11

In the Granite Gold Mine, B.C., on a vein of hard quartz from 8 inches to 5 feet wide dipping 35° to 50°, the stoping costs per ton are as follows :—

	s.	*d*.
Stoping by hand	14	0
„ by ¾-in. piston drills	11	6
„ by 2¼-in. „ „	8	4
„ by 2-in. hammer drills	6	4

Mining costs at the Elko Prince Mine, Nevada, in 1917, stoping a 2 ft. 6 in. vertical vein of hard quartz by magazine mining, using hammer drills with 1¼ in. cruciform steel, were as follows:—

	Per Ton of Ore
	$
Timbering, including ore shoots	0·5588
Blacksmith	0·0995
Stoping	0·8083
Tramming	0·2822
Hoisting	0·1956
Compressed air	0·1288
Explosives, detonators and fuse	0·4452
Repairs	0·0486
Drill steel	0·0570
Supervision, taxes, assaying, etc.	0·4987
Cost per ton	$3·1227 = 13s.

(*Bull. Amer. Inst. Min. Eng.*, Aug. 1918.)

Costs of stoping in 1903 in two mines on Cripple Creek, Col., in narrow veins: machinemen, $4; miners, $3 for 8 hour shift; coal, $4·60 per ton; timber, $20 per mil.

	I.		II.	
Machinemen and miners	$0·34		$0·369	
Shovellers and trammers	0·41		0·401	
Timbermen	0·23		0·215	
Total labour underground		$0·98		$0·985
Compressed air, rock drills, sharpening		0·15		0·179
Tramming, trams, etc.		0·03		0·034
Explosives		0·13		0·139
Timber		0·28		0·310
Hoisting and surface transport		0·23		0·254
Miscellaneous stores		0·04		0·291
Supervision and general expenses		0·23		
		$2·07 = 8s. 7½d.		$2·192 = 9s 1½d.

Drilling.

Ordinarily two men can drill double-handed 25 to 33 ft. of 1-inch holes per day in limestone, 4 to 8 ft. in granite. With double hammers 10 ft. of 2-inch holes can be drilled in medium rock.

On the Rand generally one white man and five Kaffirs run two air-drills; in some cases one white man and seven Kaffirs run three drills. Eight 6-ft. holes is considered a shift's work for two machines; these holes break on an average two fathoms of ground. The cost is as follows:—

	£	s.	d.	
One white man	1	5	0	
Five Kaffirs		15	0	
Power for two machines		16	0	
Maintenance		4	0	
Total	3	0	0	per fathom.

In Chili, with native labour, contracts are let on the basis of the number of holes drilled. The rock is moderately hard.

By hand.—1,008 man-days, by single hand work, drilled 13,855 ft. at a cost of 4·1*d.* per foot. Average amount drilled per man per day 13·8 ft.

By machine.—The actual cost of drilling for one month was as follows:—164 man-days (9 hours) with two ¾-in. air drills, drilled 5,082 ft. at a cost of 1·01*d.* per foot. Average amount drilled per man-day, 31 ft.

It is well known that drilling in siliceous rocks produces a dangerous dust, recognised as the origin of Miners' Phthisis. The amount of dust suspended in the air is tested by the Kotzé konimeter; the atmosphere is considered safe if there are less than 300 dust particles per c.c. (Final Report of Miners' Phthisis Prevention Committee, Pretoria, S. Africa; see also recent papers on Silicosis in *Trans. Inst. Min. Met.*)

The Safety in Mines Research Board has devised a filter bag connected by a flexible tube with the hole which is being drilled; this catches the particles of dust produced in drilling. (Paper No. 28, 1926.)

See 'Silicosis and its Prevention,' Haldane, Haynes, Shaw and Graham. *Trans. Inst. M.E.*, vol. xcvii., 1939. 'Dust-suppression (Pneumokoniosis) Experiments at a Kent Colliery,' by F. H. Price. *Trans. Inst. M.E.*, vol. cv., 1945, and Annual Reports of S.M.R.B., B.C.U.R.A.

Mechanical Drilling.

Drills either rotary or percussive. Rotary drills mostly of the twist-drill type confined to the softer rocks; Steavenson electric drill averages 40 ins. per minute in ironstone, uses 6 h.p. Siemens and others make small electric drills, taking 1 to 2 h.p., boring 6 to 10 ins. per minute in coal. For boring in hard rock the Brandt machine has been used in the Simplon tunnel and in some German collieries; hydraulically driven under head of 1,500 lbs. per sq. in.; bores 15 ft. per hour in gneiss. The Kellow drill, used in North Wales, is similar; has drilled 5 ft. per minute in slates.

Percussive drills are almost exclusively worked by compressed air. The drills are of two kinds: piston drills, in which the drill bit is rigidly connected with the piston rod, and hammer drills, in which the piston rod strikes on the end of the drill bit, the latter being lighter, smaller, and running at much higher speeds.

Drills may be classified by their valve action:—

1. Valve moved by external tappets.
2. " " internal "
3. " " air with auxiliary valve moved by tappet.
4. Valve moved by air.
5. Valveless, the piston itself acting as a valve.

Most modern drills belong to Class 3, but several types belonging to Classes 2 and 4 are also in use; very many hammer drills belong to Class 4.

Piston drills are further classified by their piston diameter, ranging from 2 to 4 ins.; 2¼-in. drills are largely used for stoping, 2¾ to 3¼ ins. for drifting, 3 to 3½ ins. for sinking. In 1902 70 per cent. of the drills in use on the Rand were 3¼ drills. Such drills use 60 to 90 cu. ft. of free air per minute at pressure between 60 and 90 lbs. per sq. in. A 3-in. drill evolves about 1¾ h.p., for which about 5 h.p. must be applied to the drill piston and 10 to 25 h.p. to the steam end of a direct-driven air compressor.

At the Rose Deep Mine, Transvaal, a trial run of 31 drills for 6 hours gave air consumption for 3¼-in. drills 81 cu. ft. compressed air, free air compressed to 70 lbs. pressure per minute; each drill required the consumption of 43 lbs. coal per hour to supply this air, 3·4 lbs. coal developing 1 h.p. hour. The average power of the compressor engine was 12·7 i.h.p. per drill; average drilling speed 4·5 ft. drill hole per drill per hour.

Relative air consumption of drills: –2¼-in. drill, 0·445; 3¼-in. drill, 1·000; 3 5/16-in. drill, 1·069; 3⅜-in. drill, 1·123.

Average speed of boring, including setting up, is 10 to 25 ft. per 10-hour shift. Costs of boring in hard rock in Sweden are about 8*d*. to 10*d*. per foot bored, of which 40 per cent. is for wages and 30 per cent. for power; average boring speed is 5 ft. 6 ins. to 8 ft. per hour for downward holes and 4 ft. to 6 ft. 6 ins. for upward holes.

Hammer drills use 25 to 50 cubic feet of free air per minute; speed of boring about the same as piston drills, but holes are usually smaller. Hammer drills with a relatively rapid turning action of the bit and using bits with a chisel edge, but specially twisted steel, are used very successfully in coal. Hammer drills are replacing piston drills for stoping, etc.

A complete 6-piston drill plant costs about 500*l*.

Two-stage compressors, delivering air at 100 lbs. gauge pressure weigh on the average 27 lbs. and cost on the average 12*s*. in the U.S.A. per cubic foot piston displacement.

In the case of small quarry plants or contract work, where drilling is done in the open, dry steam at a pressure of from 80 to 100 lbs. can be used, but will not give such good results as compressed air. Where a number of drills are used, a compressed air plant should preferably be installed, and is indispensable in underground drilling. With a properly laid pipe line of suitable size, there is very little loss in conveying compressed air from a central plant over very large distances.

Detachable drill bits are said to give good results at several large mines, saving in cost of transport of drills. (*Trans. Amer. Inst. Min. Eng.*, 1930 Year-book, p. 139.)

Sharpening Steel Bits.

A good blacksmith and striker can sharpen 30 to 40 bits per hour.

By the use of power drill-sharpeners, many of the shortcomings attendant upon the hand-sharpening process are got rid of, and drills can be kept true to gauge, with the result that where these machines are used it is possible to accomplish more drilling, whilst the cost of sharpening is considerably reduced. There are a number of drill-sharpening machines on the market.

EXAMPLE.—Required the amount of free air necessary to operate thirty 5-in. 'H' drills at 9,000 ft. altitude, using to operate these drills air at a gauge pressure of 80 pounds per sq. in.

From Table I we find, when operating the drills at 80 pounds gauge pressure at sea level, that one 5-inch 'H' drill requires 190 cubic feet of free air per minute.

From Table II we also find that the factor for 30 drills at 9,000 feet altitude is 20·38; multiplying 190 cubic feet by 20·38 gives 3,872 cubic feet air per minute, which is the displacement of a compressor for the above outfit under average conditions, to which must be added pipe line losses, such as friction and leakage. See also 'Problems of Mechanical Coal-Mining,' by S. Mavor, *Trans. Inst. Min. Eng.*, vol. lxvii., p. 456.

According to experiment, the fastest cutting bit is the Carr (double chisel bit with central hole), the Z, + and 6 edged star in this order; cutting speed $\propto$ (drill diameter)$^{-2}$; cutting speed $\propto$ air pressure; pressure of 85 lbs. per square inch most generally satisfactory.

(*Bull. Amer. Inst. Min. Eng.*, August 1917, p. 1079.)

Air Receivers.

An air receiver is not intended so much for storage as to equalise pressure, and to allow of an even flow of air through the pipe, there being a certain amount of pulsation from the air compressor discharge itself. In long pipe lines a smaller receiver should be placed in the pipe line near the point of application of the compressed air, furnished with suitable drain cocks, for the purpose of drawing off the superfluous moisture which might collect, and the consequent prevention of freezing in the line. The following table gives sizes and details of receivers which are usually considered standard practice :—

Large-scale Distribution of Power by Compressed Air.

The Powell Duffryn Colliery Co. in South Wales distribute compressed air to collieries 8 to 10 miles away from their Bargoed Colliery at 80 to 85 lbs. pressure by a system of welded steel pipes varying in diameter from 28 to 12 ins., the compressed air being produced by three 40,000 cub. ft. per minute steam turbo-compressors, each turbine developing 7,000 h.p. at full load. It has been calculated that the pressure drop at the pit top would not exceed 10 per cent. when all the collieries were taking their maximum load. Under normal conditions the drop in pressure over 9 miles transmission is about 5 per cent. This good result is secured by using large pipes with consequent low velocity of air. A number of expansion joints are provided in the pipe line.

HAULAGE.

Practice in haulage varies greatly from the best to worst in British collieries. The great majority of collieries use rope and tub haulage, with or without belt conveyors to a central loading point, and the coal stays in the tub until it is tipped at the screens. The obvious waste involved in winding tubs as well as coal can be overcome only by extensive re-equipment, which may not be justified in many cases. Similarly with underground haulage, the cost of reconditioning roads and change of layout required to suit improved methods of haulage is often prohibitive.

As an example of best present day practise in a pit not recently sunk that installed at Manvers Main Colliery serves well.*

Coal from the Haigh Moor Seam, $4\frac{1}{2}$ ft. thick at 347 yds. depth and average dip 1 in 17, had been wound in tubs in ordinary cages from 1942 to 1945, when skip winding was put in operation,

* 'Coal Handling from Face to Screens at Manvers Main Colliery.' Payne & Kimmins. *Trans. Inst. Min. Eng.*, November 1948.

together with an improved haulage system. The four actual workings, all in one district, are advancing longwall faces, each 250 yds. long double-unit, and producing some 500 tons per turnover of 5 ft. Face equipment, which is identical on all four faces, comprises two 24-in. troughed belt conveyors driven by 15 h.p. motors. These face conveyors deliver on to a short-scraper chain conveyor in the centre-gate, which feeds the gate conveyor proper. The interposed all-steel conveyor saves the gate belt from damage at the delivery end, and its cost and charges are fully recovered thereby. The gate conveyors are 30-in. fully troughed belts carried 12 ins. above floor level and driven by 40 h.p. motors at 310 ft. per min.; when the length of haul necessitates its extension conveyors will be arranged in tandem.

The layout of the faces is such that two gate conveyors deliver on to the trunk belt at the same position, from opposite sides, on to a belt already carrying the output of faces inbye. In order to mix the coals from different faces, and to load the belt centrally to avoid spillage, transfer points were arranged. The trunk belt is deflected in such a way that all three belts feed into a hopper which discharges the mixed coal on to the trunk belt again. Dust is suppressed by hoods and water sprays.

The trunk belt is 42 ins. wide and 650 yds. long, driven by a 75 h.p. 3,300 volt slip-ring motor at 380 ft. per min. through a worm reduction and fluid coupling. An ultimate length of 2,500 yds. is envisaged, requiring tandem belts up to about 800 yds. each. Concrete was used for the foundations of the drive head and motor, and for the conveyor structure, which carries the bottom belt 1 ft. clear of the floor. The belt is of six-ply 32 oz. duck with $\frac{4}{64}$-in. top and bottom covers, and the joints are vulcanised.

At the loading point the trunk belt delivers to the mine cars through a shaker chute of 8 tons capacity, which serves both as a reservoir and feeder to the mine cars. The chute is driven by a 15 h.p. motor at 88 by $3\frac{1}{2}$-in. strokes per min., and dust is suppressed by complete hooding and four water sprays.

The all-steel cars, which are of 6 tons capacity, during their passage through the loading point are attached to a twin chain creeper driven by a 13·5 h.p. variable speed air motor fitted with an air brake. Coal is loaded at the rate of 625 tons per hour at peak periods, and 65 to 70 cars are filled each hour at the busiest part of the shift. Control of the loading point is carried out from a station built on the opposite side of the road from the trunk belt, where the operator has all the controls arranged before him, and can inform the pit bottom of the number of cars filled per hour.

The cars are 18 ft. long over the couplings, 16 ft. 3 ins. long in the body by 5 ft. 3 ins. wide and 4 ft. 6 ins. high; they are of fabricated construction, and 2 tons 16 cwt. tare weight. Automatic couplings are used and the clearance between the tops of adjacent cars is 1 ft. 8 ins. The two axles are at 5 ft. 6 ins. crs. have 16-in. dia. wheels.

Two diesel locomotives are required to operate the trains, and one is kept in reserve. They are 100 h.p. 0–6–0 type of 15 tons weight, with four gears, giving a top speed about 15 m.p.h. and a maximum tractive effort about 8,000 lb. An underground depot is provided for servicing and maintenance repairs to the locomotives.

The engines each use about 0·43 gals. of fuel oil per mile, and the total cost per ton of coal hauled is:—

0·14*d.* for fuel oil.
0·01*d.* ,, lubricating oil.
0·10*d.* ,, maintenance;

these costs include non-productive mileage as in hauling mine dirt on back-shifts.

A 36-in. gauge track laid with 65 lb. flat-bottom rails dogged to larch sleepers 5 ft. 10 ins. long by 10 ins. by 5 ins. set at 2 ft. 10 ins. crs. Ballast is of mine rock and ashes graded from $1\frac{1}{2}$ ins. down, and laid 10 ins. deep from 1 in. below sleeper level. Track maintenance required 2 men for 5 shifts a week initially, but this should be halved as the track settles.

Five trains of 15 cars each are used, each train in charge of an engine driver and a guard, who stands on a platform at the rear of the train and signals the driver by coloured lamp and by whistle.

The full trains gravitate on a gradient of 1 in 80 from the creeper at the loading point into a shunt. There they are coupled to the locomotive and hauled 800 yds. against an adverse gradient. The train of cars alone is then lowered back down a slant road 375 yds. long and leading off the main road, to the dumping point for the skip; after discharging the train returns by gravity to the loading point, 370 yds. farther along that slant.

The dump consists of a hopper built under the track, with capacity rather greater than that of one car. Into this the car discharges through bottom doors, which are closed again by a ramp as the car leaves the dump. The cars are moved across the dump by a creeper working against a gradient of 1 in 100, and driven by a 10 h.p. electric motor which is controlled by a pneumatic clutch. One onsetter controls the movement and discharge of the cars into the dump, and the subsequent charging of the coal into the skip then in juxtaposition.

The skip winding plant was adopted to replace the original cage. The skip itself is 34 ft. long by 9 ft. by 3 ft. 2·5 ins., it weighs 8·5 tons and holds 6 tons of coal, *i.e.* it has the same capacity as a mine car. A locked coil winding rope 1·625 in. dia. gives factors of safety 8·5 static and 6·8 kinetic. The scheduled number of winds is 50 per hour, giving a lift capacity of 300 tons per hour.

At the surface the skip automatically discharges itself through a bottom door into a bunker. from which the coal is conveyed to the screens by a 48-in. belt running at 190 ft. per min. At the surface one banksman alone is required ; otherwise conveyance from pit-head to screens is wholly automatic.

In the result it is claimed that this reorganisation requires 74 less men than would intenser working of the previous system of rope haulage and cage-winding, and the O.M.S. on conveying from coal face to screens increased from 19 tons to 87 tons.

Rails.

Mine rails for tub haulage weigh 10 to 10 lbs. per yard. The following table shows the least weight that should be used for the given loads (weight of 1 loaded tub) and low speeds :—

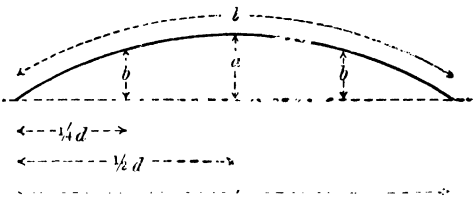
Loads, in cwts.	7	10	15	20	25	30
Weight of rails per yard, lbs.	10	12	15	18	20	22
Gauge of track, in inches	15–18	15–18	16–20	18–22	20–26	20–30

For speeds above 5 miles per hour heavier rails are to be preferred.

Weight of 1 mile of single track in tons = 1·571 × weight of rail in lbs. per yard.

Sleepers 2 ft. 6 ins. to 3 ft. 6 ins., usually 3 ft. apart.

Sleepers 8 ins. to 12 ins. longer than gauge of track, 3–4 ins. deep, 6 ins. wide. A pair of fishplates and 4 bolts for 18 lb. rails, weigh 4–8 lbs., usually 5 lbs. ; 100 dogspikes for same weigh **about 14 lbs.** Weight of fishplates, bolts and spikes is approximately 1 cwt. per ton of rails.



To bend rails to any curve, let l be length of rail, r radius of curve, both in feet, a the middle ordinate in the centre of the curve, b the quarter ordinate, midway between a and the end of the rail (both a and b in inches):—

Then

$$a = 1{\cdot}56\,\frac{l^2}{r}, \qquad b = 1{\cdot}17\,\frac{l^2}{r}.$$

Width of track ¼ in. to ¾ in. greater than gauge of wheels.
Additional width round curves :—

Gauge of track	15	18	24	30 ins.
Additional width	¼	½	⅝	¾ in.

In the case of curves, in all forms of haulage except in regard to main-and-tail-rope haulage (because of the pull exerted by the fore-end rope) the outer rail is raised, in order to prevent the tendency of the tubs to fly off the track. An empirical formula for a suitable elevation in inches E is given by :

$$E = \frac{3DV^2}{3r} \text{ where } V = \text{velocity of tubs in feet per sec.; } D = \text{gauge of track in feet; } r = \text{mean radius of curve in feet.}$$

Tub Control.

A pneumatic system for the remote control of tubs has been in use for some time.

The principle is that two channels fitted with replaceable rubbing strips, arranged parallel with the track and one on each side, engage with the outer faces of the four wheels above the level of the axle, thus applying a steady braking action.

The two channels in each unit are mechanically coupled to pneumatic cylinders situated centrally beneath the track, and set in concrete, 12 ins. excavation being necessary for this purpose.

According to the position of the control valve, either the pneumatic cylinder will be subject to pressure and will close the channels into the braking position, or the pressure will be released in the cylinder, and the channels will be opened out by the return springs.

A similar system, operated hydraulically, has been introduced by Dowty Mining Equipment, Ltd., in which ten such braking units can be run from one 5 h.p. electric motor and pump.

Coefficient of friction of tubs on well-kept mine road (level), 1 per cent. to 3 per cent., average say 1·5 per cent. ; with tubs badly greased on roads in bad condition may be two to three times as much. Coefficient of sliding friction (wheel spragged) is from 12 to 20 per cent. ; if m be coefficient of rolling friction, m' of sliding friction, the coefficient of friction with :—

$$1 \text{ wheel spragged} = \frac{3m + m'}{4}; \quad 2 \text{ wheels spragged} = \frac{m + m'}{2} \quad 3 \text{ wheels spragged} = \frac{m + 3m'}{4}.$$

Additional friction in going round curve of radius r, where the gauge of the track = s (both in feet) is $\frac{s}{2r}\,m'$.

Tractive effort with 18-in. wheels on good level track, 40-in. gauge, at 5 to 6 m.p.h. = 24·3 lbs. per ton with plain bearings, 12·8 lbs. with roller bearings. (*Trans. Amer. Inst. Min. Eng.* vol. lv., p. 29.)

A wooden tub with plain bearings at speed of 1·75 m.p.h. showed coefficients of friction :—

$\frac{1}{30}$ with poor, $\frac{1}{54}$ with average, $\frac{1}{78}$ with good lubrication.

Coefficient on starting from rest with average lubrication $\frac{1}{30}$; tests with plain bearings at collieries gave $\frac{1}{20}$, $\frac{1}{33}$, and $\frac{1}{58}$ respectively. A steel tub with plain bearings gave $\frac{1}{58}$, with Climax bearings $\frac{1}{60}$, with Skefko ball bearings $\frac{1}{135}$; tub with Rowbotham wheels $\frac{1}{86}$.

A 9-ft. radius curve trebles, a 12 ft. radius curve doubles, the coefficient of friction with fixed wheels; loose wheels give ¾ of increase of fixed wheels.

Starting effort to get up to a speed of 1·75 m.p.h. = 2 to 3 times the effort required to maintain that speed with plain bearings, 1½ to 2 times with Rowbotham wheels, and 1 to 1½ times with Skefko ball bearings. (J. Wilson, *Trans. Inst. Min. Eng.*, lxiii., p. 294.)

With 'wheel' greasers the consumption of grease averages about ¼ lb. per tub per diem for ordinary collieries.

On the average a putter can put 10 tons of coal over a distance of 200 yards (level) in an 8-hour shift.

A horse does its best work when travelling at a speed in feet per second $= \frac{1}{4} h$, where h is the height of the horse in hands, and exerting a pull in lbs. of $\frac{60 c^2}{h}$, where c is the circumference of the horse's chest in feet (*Baron*). Average pull is about 1¼ cwt.

Maximum gradient for hand putting, 17 per cent.

Maximum gradient for horse haulage, 12 per cent.

Gradient at which resistance of full tub downhill equals that of empty tub uphill:—Let W be the weight of a loaded tub, w that of an empty one, θ the inclination of the road, μ the coefficient of friction :—$\tan \theta = \frac{\mu (W - w)}{W + w}$ (usually $\tan \theta = 0{\cdot}015$ about).

Work done in hauling a tub of weight W up or down an incline of length $l = l(\mu W \cos \theta \pm W \sin \theta)$

Self-acting Incline.

Self-acting Incline.—Let the sets consist of n tubs each of weight w lbs., and capable of carrying W lbs. of mineral. In the case of over-tub haulage the weight of the rope (or of the chain as the case may be) must be included in W. Let the slope of the incline, assumed uniform, be $\alpha°$. Let l be the length of the rope (= length of incline) in feet, c its weight in lbs. per foot.

Let the rope be supported on rollers, the weight of which per foot of rope (= weight of one roller divided by the distance in feet between the centres of successive rollers) is r lbs.; r must include the weight per ft. of the rope resting on the rollers. Let D be the diameter of the rollers d of the spindle. Let μ be the coefficient of friction of the tub on rails (usually say about 0·015) and μ_1 the coefficient of friction of lubricated bearings (say 0·05 to 0·08). Let F be the frictional resistance of the drum at the head of the incline, including that of the rope coiled upon it—a figure that is always relatively small and may often be neglected. Then at any distance x feet from the starting point the full set is just able to move down the incline when :—

$$\tan \alpha = \frac{\mu n (W + 2w) + \mu_1 l (c + r) \frac{d}{D} + F}{nW - c(l - 2x)}$$

By putting $x = 0$ the above expression gives the angle at which the set will just start from the top of the incline.

The time occupied in descending a distance x will be :—

$$t \text{ seconds} = \sqrt{\frac{2x[n(W + 2w) + (c + r)l + M]}{g\left[\sin \alpha (nw - cl) - \cos \alpha \left(l(c + r)\frac{d}{D}\mu_1 + n(W + 2w)\mu\right) - F\right]}},$$

and the velocity in feet per second v attained after travelling a distance of x feet will be :—

$$v = \sqrt{\frac{2gx\left[\sin \alpha (nw - cl) - \cos \alpha \left(l(c + r)\frac{d}{D}\mu_1 + n(W + 2w)\mu\right) - F\right]}{n(W + 2w) + (c + r)l + M}},$$

where M is the weight of the drum and its fittings and g the acceleration due to gravity.

All the above expressions are approximations, but are accurate enough (too large) for practical purposes.

When the slope is not uniform, the calculations become more complicated. If H be the total vertical fall of the incline and L its horizontal length, it is usually sufficient, with the low gradients prevailing in collieries, to use the above formulas, putting $\alpha = \tan^{-1} \frac{H}{L}$. As the denominator of the expression given above for $\tan \alpha$ increases with x, it is obvious that the incline should, whenever possible, flatten going downwards, or be concave, though not so much

so as to cause the rope to rise too high above the rails. The exact shape of the curve is not very important; it may with advantage be a parabola, which may be set out by making the height h at any point distant y ft. horizontally from the foot of the incline $= \frac{y^2H}{L^2}$. The rope will then follow the curve whenever the relations are such that $H = \frac{cl^2}{4T}$, where T is the tension of the rope. From the above expressions the power required to drive any type of haulage can readily be obtained.

Main-and-Tail Rope Haulage.

Main-and-Tail Rope Haulage.—Loaded tubs in sets up to 40 are hauled outbye by motor (steam-engines, compressed-air engines or electro-motors) at speeds up to 20 miles per hour, whilst the empty tubs are hauled inbye by means of the tail rope. The size of the engine depends upon the pull to be exercised when one set (nearly always the full set) is in its least favourable position. Let T be the tension in the rope in such position, made up of the weight of the set plus rope × sine of angle on inclination of the roadway, the friction of the set and of both ropes on the rollers and the pull required to accelerate the moving parts. Let O be the diameter of the steam cylinder in inches, one of which is alone assumed to be effective at the start, let K O be the stroke of the engine in feet (K is usually $\frac{1}{4}$ to $\frac{1}{3}$), S the steam pressure in lbs. per sq. in., s the ratio of the number of teeth in the spur wheel on the drum shaft to the number of teeth in the pinion on the crankshaft, D the diameter of the drum in feet, then

$$O = \sqrt[3]{\frac{4DT}{\pi SKs}}$$

For any portion of the trip except the start (i.e. with set already in motion), both cylinders are effective, and the value as found above must be divided by $\sqrt{2}$.

These engines are usually small and run at a piston speed of 500 to 800 ft. per min.

Endless Chain and Endless Rope.

Endless Chain and Endless Rope.—Endless chain is now rarely used except on steep gradients and for short distances; it is less reliable than endless rope on long roads, requires more power and is rather more expensive to work, but admits of rather higher speeds; it may work up to 6 miles per hour; endless rope rarely exceeds 4 miles.

The following calculations apply to both methods unless otherwise stated:—

If Q be the quantity of mineral in tons to be transported per hour, W the weight in lbs. carried by one tub, V the speed of haulage in miles per hour, f the distance apart of the tubs in feet, then

$$f = 2{\cdot}36\,\frac{V \cdot W}{Q}.$$

Endless chain is always over-tub haulage, endless rope may be over-tub, under-tub or side-tub. In over-tub haulage the tubs must be so near together that the rope does not touch the ground between them. Let T be the least tension in the hauling rope or chain (*i.e.* between the two tubs nearest the driving pulley on the empty side), let c be the weight of the rope or chain per foot, h the height of the tub, then the distance f_1 of the tubs apart is given by

$$f_1 = \sqrt{\frac{8hT}{c}}.$$

If f is greater than f_1 empty tubs must be run on the full side.

The pull to be exerted by the engine driving the haulage is

$$\mu\left[n\,(2w + W) + 2c\,.\,l\right]\cos a \pm W \sin a,$$

using the same notation as above, n being the number of tubs on any one side of the rope at any time, so that $n = \frac{l}{f}$; the lower sign is used when the gradient is with the full tubs, the upper one when against it. If this expression has the − sign, the arrangement is self-acting.

The return wheel of an endless rope haulage is often used as a tightening pulley, being capable of sliding and pulled by a weight W.

Let the radius of the pulley, fig. 4, be R and of its spindle r.

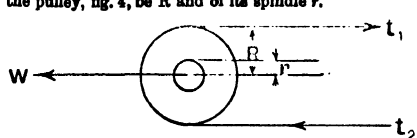


FIG. 4.

Let the coefficient of friction between the spindle and its bearing be μ.

Let the tension in the rope coming off the pulley be t_1, and in the rope leading to the pulley be t_2,

then,

$$W = t_1 + t_2; \qquad R(t_1 - t_2) = r\mu W$$

whence

$$t_1 = \frac{W}{2}\left(1 + \frac{\mu r}{R}\right); \qquad t_2 = \frac{W}{2}\left(1 - \frac{\mu r}{R}\right)$$

Locomotive Haulage.

Locomotives are being used on an increasing scale to replace older methods of rail transport and conveying on main roads. They require large, well-graded, and fairly straight roads and the initial cost of installation can be quickly recovered in suitable applications. The advantages obtained are higher speed and weight of coal hauled with fewer men engaged; two-way hauling and man-riding are feasible, and may effect very considerable economy; also greater flexibility is obtained with less power used. Average speeds of 8 to 10 m.p.h. can be obtained, on the flat or with gradients not exceeding 1 in 15. Where braking is a controlling factor a maximum gradient of 1 in 25 is recommended.

The rolling resistance of the loaded tubs or cars is of vital importance in locomotive haulage On straight level track, with both track and cars in good condition, the rolling resistance varies from 15 lb. to 30 lb. per ton for plain bearings; with taper roller bearings the resistance is about 7 lb. per ton. Starting resistances may be higher by 10 lb. per ton, and curves of the order of 45 ft. radius may increase these resistances by 15 lb. per ton. Curves of about 22 ft. minimum radius can be negotiated when hauling loaded trains on tracks up to 36-in. gauge (see also p. 891). The choice between the several different types of locomotives, *e.g.* electric, diesel, etc., depends chiefly on the gradient, load to be hauled, and mining conditions—with special regard to ignition hazards and health requirements.

Electric Locomotives.—It is accepted that the overhead wire, or 'trolley' locomotive is the most efficient form of traction for use in mines when all conditions are favourable. This arises from the fact that it derives its power from an external source, and that power is readily converted to the rotary motion required for propulsion. Maintenance charges are less than in locomotives with reciprocating parts, and no noxious fumes are emitted. But, owing to the risk of ignition by contact arcing, no trolley locomotives are used in British collieries under existing regulations under the Coal Mines Act; the pertinent regulations are, however, being reconsidered.

Either A.C. or D.C. may be used.

Locomotives of 85 h.p. are used in the Ruhr, and in U.S.A. some have two motors of 150 h.p. each or four of 95 h.p. with weights up to 32 tons. At 75 per cent. efficiency of conversion and 25 per cent. coefficient of adhesion the latter type has a tractive effort of 18,000 lb. and a maximum speed of 8 miles per hour.

Battery-operated Electric Locomotives.—Lead-acid accumulators with a useful life of at least three years are used, and the power output is from 3 to 6 h.p. per ton of locomotive weight. The few used in this country are of small power, but engines up to 40 and 65 h.p. are used in Germany and in U.S.A. Within a limited field the electric battery locomotive is an economical proposition.

Compressed Air Locomotives.—Engines of 40 h.p. with a length of haul of 1,500 yds. are used in the Ruhr. They are intrinsically safe and the exhaust refreshes the atmosphere underground. The air supply is drawn from reservoirs at either end of the run at pressures of 600 to 1,000 lb. per sq. in. It is reduced to 150 lb. at the valve chest. The engine and valve motions are similar to those for a steam locomotive of similar size.

Diesel Locomotives.—The use of this type of engine is extending rapidly in Great Britain, as it provides an extremely flexible system of haulage, and it is the best available under the present Electricity Regulations of the Coal Mines Act, 1911. When properly equipped and maintained these engines can be operated with a high degree of safety in return or intake airways.

Rail gauges of 24 ins., 30 ins., and 36 ins., are to be standardised by the N.C.B. and all of these will probably be used for Diesel haulages. The 0–4–0 and 0–6–0 types of locomotive are used, driven by gearing through a jack shaft with coupling rods, or by chain, to 24 in. dia. road wheels. Several manufacturers are now making them, *e.g.* North British, Fowler, Hunslet, Ruston & Hornsby, in units up to 165 h.p. The Hunslet Engine Co., produces four types, of 16–24, 65, 70, and 100 h.p. In some of these the entire frame is a single-piece casting in steel or high-duty cast-iron, the casting including considerable parts of the gear-box and other components. A friction clutch and four gears provide speeds of about 4, 6, 9 and 14 m.p.h. The 70 h.p. engine weighs 10 tons and has a maximum tractive effort of 5,400 lb. while the 100 h.p. engine weighs 15 tons and has tractive effort of 8,000 lb. An air compressor is driven from the engine to supply air for Westinghouse brakes and for the starting motor: a screw hand brake is also provided. A flame-proof 12 volt dynamo supplies the lamps.

F. 895

The engine exhaust goes through a stainless steel water bath, and then passes out through a stainless steel flame arrestor to atmosphere on the side remote from the driver. Other makers use a water-cooled exhaust system with special filters and flame traps. These devices ensure safety in respect of flame-proofing. The effect of CO and NO_2 and obnoxious smells on health has to be remedied by dilution by adequate ventilation.

New regulations under the Coal Mines Act, 1911, are shortly to be issued by the Minister of Fuel and Power to govern the use of locomotives underground ; in particular the permissible percentage of CO and NO_2 emitted by diesel engines will be stipulated.

Diesel locomotives have outstanding advantages over other systems ; the initial cost is much less : operating costs for fuel and maintenance are low, and these apply to large or small and concentrated or diffused installations, whether working intensively or at less than full capacity.

Conveyor Haulage.—The normal practice on longwall faces in British mines is to convey the coal off the face, and deliver it at the centre gate either direct into tubs or on to a gate conveyor : in the latter case the conveyor fills the tubs at a central loading station. Belt conveyors are more in favour and more widely used for all purposes than are the older types of scraper-chain or shaker conveyors. The troughed-belt type which is mostly used in the gates, will negotiate inclinations of 18°.

The conveyor system has the drawbacks of high initial cost, and it must be fully loaded for economical working ; also the transport of materials and supplies inbye usually requires a tub-track, and man riding is prohibited. Its advantages are silent and continuous running, its ability to follow the gradients of the seam, less men employed and fewer accidents. Roadway maintenance is also easier and less expensive with conveyor than with tub or locomotive haulage.

WINDING.

In sinking pits, the excavated material is usually hoisted in steel buckets or hoppits, generally unguided, and commonly single. The load is thus wholly unbalanced, geared engines are often used, and the winding speed is slow. Such buckets have capacities of 25 to 50 cubic feet, say 30 to 60 cwts., the weight of the bucket being from ¼ to ⅓ of its load. For ordinary colliery work cages carrying two to twelve tubs are used, always in pairs running on wooden, rail or rope guides ; in collieries in U.S.A. large skips are sometimes used instead of cages. (See paper by H. F. Hebley, *Trans. Inst. Min. Eng.*, vol. lxxxiv., p. 222.)

Practically the whole output of coal in Great Britain is still cage wound, the tubs ascending with their loads of coal. The policy of the National Coal Board is to apply skip winding where practicable in new sinkings and conversions. This system is already used in this country on a small scale and on a larger scale in the Ruhr, Poland, and in U.S.A. where skips of up to 12 tons capacity are used, as compared with 10 tons in this country.

Where cage winding is installed and giving satisfactory service there is no object in applying skip winding. But in cases where an increase in output is not possible with cage winding, then skip winding shows the following advantages.*

The proportion of pay load to total load is raised by about 40 per cent. (*e.g.* from 34 per cent. to 48 per cent.), and loading and unloading are faster, thus increasing the capacity of the shaft ; less labour is required at decking levels ; simpler lay-out of pit at top and bottom ; fewer tubs or cars needed and the size of car used underground is not restricted by the size of cage ; also the rope is in tension always and not subject to snatch. The chief disadvantages are the difficulty of keeping separate coals of different qualities, and that of winding men and materials with a skip, which may often require one shaft to be equipped with cages. Anti-breakage devices appear competent to prevent excessive breakage with skip winding. Plants with capacities for winding up to 3,000 tons in a 7 hr. shift from depths exceeding 2,000 ft. are at work in this country, and much higher capacities, up to 1,000 tons per hour from a depth of 600 ft. are used in U.S.A.

Nearly all of the skips used in collieries in this country are adapted to shafts designed for cage winding (sometimes with one cage still working), with the main object of increasing the shaft capacity, and their design has been influenced thereby. The plan dimensions are similar to those of an equivalent cage, but the length may be greater. The length has to accommodate the side discharge chute and its control doors, as well as the side loading aperture.

Ordinary structural steel sections and plates ¼ in. to ⅜ in. are used for the body, with either welded or riveted construction. High tensile steel plates backed by softwood linings 1-in. thick may be applied to surfaces subject to wear by abrasion ; they last from one to two years.†

Anti-breakage devices are usually in the form of hinged flaps operated by spring and dashpot gear, or the latter combined with counterpoises. These devices also reduce the shock on the rope when the skip is loaded. The bottom doors of the skip are operated and locked by levers with

* For a description of one of the first plants in this country, see 'Skip Winding at Barnborough Main Colliery,' by G. O. Payne, B.Sc., M.I.Min.E., N.A.C.M., 1944.

† See 'Seven Years' Experience of Skip Winding,' by Col. E. Hart, M.C. *Trans. I. Min. E.*, vol. cv., Pt. 6, 1946.

spring catches; and in the Ruhr an improperly closed door trips a catch in the shaft which stops the wind.

When a rope haulage system is retained, with tubs holding 10 cwts. to 20 cwts., tipplers are used to load the skip. The tubs are picked up by a creeper elevator and passed on at a regular rate into the tippler, two tubs at a time. The coal enters a pair of hoppers or measuring pockets, of which one feeds each of the two skips. One onsetter attends to all these operations at pit bottom. The empty tubs pass from the tippler back to a standing line for redistribution to the districts. At the bank, the skip is discharged automatically into a bunker, from which it is fed on to a belt conveyor and passed to the screens.

When feasible a haulage system using large drop-bottom cars holding 3 to 6 tons is preferred. Loading arrangements comprise a dumping hopper of rather greater capacity than the skip at each loading level. The cars are moved over the hopper by a creeper or a retarder, or by air or oil operated piston pushers. The operation of these devices is interlinked with that of the auxiliary equipment, such as door strips and anti-spillage plates, and is placed under the control of one man.

In Great Britain the weight of coal relative to total weight of coal and cage, etc., is about 35 per cent. for cage winding, and about 50 per cent. for skip winding. On the Continent lighter equipment enables these figures to be increased to about 40 per cent. and 55 per cent.

Cages made of duralumin instead of steel have been used for the sake of lightness.

Slack adds greatly to strain on rope.

The velocity of winding varies from 15 to 75 ft. per second; a rule given by O'Donahue is: allow a speed of 20 ft. per second for shafts up to 200 yards in depth, and add 5 ft. per second for every additional 100 yards.

Wooden guides are usually 3 ins. × 4 ins. to 4 ins. × 6 ins.; rail guides 50 to 70 lbs. per yard. Rope guides made of single strand of 7 to 15 wires each $\frac{3}{8}$ to $\frac{1}{2}$ in. diameter, stretched by weight of 1½ to 5 tons; weight is often calculated at 1 ton for every 250 yards depth of shaft. The weights should differ somewhat from rope to rope. The friction on the guides is but small: it usually amounts to about 0·025 of the total load **on the rope with wooden or rail guides and 0·02 of the load with wire rope guides.**

Koepe Pulleys.

The Koepe system is almost universal in Germany and Holland as an economical, safe, simple and flexible method of winding, better suited to their needs than drum winding; it is now arousing growing interest in this country. This system consists of a steam or electrically-driven wheel with a suitably lagged groove in its periphery to take a single winding rope. The Koepe wheel may be mounted in an engine house at ground level, or on the headgear, when it replaces the usual pithead pulley. The cages or skips are suspended one on each end of the rope which passes over the Koepe wheel; the arc of content of the rope around the wheel is always less than 360°, and usually between 180° and 230°. To effect complete balance of the system, a tail rope is used, joining the bottoms of the cages. This rope which is usually heavier than the winding rope and may be flat or round, hangs freely in the shaft and passes round a guided pulley (or a mere timber baulk) set at a position below the lowest winding position of the cages. The ratio of total suspended load to the useful or out-of-balance load is 3·2 to 1 minimum.

Hence all weights other than the useful load are balanced, and the power required is that to raise the load, overcome friction and accelerate or retard the moving masses; the latter are, of course, much less than with drum winders.

The Koepe system is best suited for winding heavy nett loads from deep levels (not less than 1,000 ft.) and is not suitable for multi-level winding. It is, however, more readily adaptable to winding from deeper levels in the same shaft than is drum winding. The risk of slip or creep between the Koepe wheel and the winding rope can be effectively guarded against; first, by using suitable material in the rope groove (*e.g.* leather, rubber, bonded fibre, or special aluminium alloy inserts); secondly, by limiting the rates of acceleration and retardation to induce frictional forces not exceeding 0·2 compared with 0·3 to 0·8 coefficients of friction given by the linings named above; and thirdly, by the right choice of rope and proper attention to its treatment and cleaning.

Regulations in Germany allow a statutory life of 2 years for a rope on a Koepe winder, as compared with 3 years and 6 months under British regulations for a rope on a drum winder; but the latter uses two ropes and the former only one.

The first Koepe winder, supported directly over the shaft, thus dispensing with the usual headgear and pulleys, to be erected in this country, is in operation at Plenmeller Colliery, Northumberland. The Koepe driving pulley is 11 ft. 6 ins. in diameter, driven through single reduction gearing at 200 r.p.m. by a 240 h.p., d.c. motor, fitted with Ward-Leonard control. Current is supplied by a 200 kW., 350 volt generator direct coupled to a 3-phase 50 cycle 600 volt induction motor running at 730 r.p.m. The depth of the shaft is 815 ft., and single deck cages taking 3 tubs holding altogether 48 cwts. of coal are used. The whole of **the hoisting machinery**

is contained in a two-storied steel-framed house with corrugated iron sides and roof mounted on a tall lattice-girder framework. An overall efficiency of 60 per cent. is attained.

(*Trans. Inst. Min. Eng.*, lv., p. 170.)

Another has been working for 25 years at Murton Colliery, Co. Durham. The motor here is 400 h.p. on a 2,000 volt, 40 period current; it draws 4 tons of coals per wind from a depth of 1,431 ft. in 80 secs. The coefficient of friction between rope and driving pulley has been found to be 0·407. The overall efficiency is 61 per cent. (G. Raw, *Trans. Inst. Min. Eng.*, vol. lxxiii., 1927, p. 380).

On the Rand hoisting with skips costs 8*d*. to 1*s*. per ton from depth of about 1,000 ft.

ROPES FOR HAULAGE AND WINDING—See Section XXI, Part III, page 933 (Vol. I).

The time of banking varies considerably; it may be averaged at about 10 to 15 seconds for one deck and 25 to 45 seconds for double decks. Up to 3,000 tons may be wound in 10 hours, but 2,000 tons is not often exceeded.

The consumption of coal in winding engines varies from 0·5 to 1·5 per cent. of the weight of coals wound. Steam consumption 50 to 100 lbs. per shaft h.p. hour.

The cost of a winding engine and boilers erected varies from about 3,500*l*. to about 10,000*l*.

The cost of winding, exclusive of interest and depreciation on the winding plant, varies from about 3*s*. to 10*s*. 6*d*. per 100 tons wound.

Professor S. M. Dixon and Mr. M. A. Hogan have published some measurements of the kinetic loads on colliery winding ropes (Safety in Mines Research Board Paper, No. 78). They state that with steam winders in shafts of moderate depth the total tension on the rope may be as much as two and a half times the dead load, furthermore that the fatigue resistance of hard-drawn steel wire to repeatedly applied tensile stresses is of the order of one-half of the strength shown by a static tensile test. Hence the factor of safety of such ropes is reduced from 8 or 10 to 1·6 or 2, and may be still further reduced by surface damage and corrosion. It has been found that a few inches of slack add considerably to the strain on the rope, as shown by the following table, which gives the average multiples of dead load for a given amount of slack:—

Slack.	*Multiples of dead load.*
3 inches	1·61
6 „	2·14
9 „	2·47
12 „	2·71

Much information will also be found in a paper on 'Mechanical Braking and its Influence on Winding Equipment,' by J. F. Perry and D. M. Smith. *Proc. I. Mech. E.*, vol. cxxiii., pp. 537–620; 1932.

Electric Winding Plants.

Electrically actuated winding engines are being increasingly used at collieries and metalliferous mines. The alternating current (A.C.) generated or received at the mine may be either utilised as such to drive the winding motor or it may be converted into direct current (D.C.). Although the efficiency of the direct drive by three-phase motor is usually higher than in systems where conversion to D.C. is necessary, it sometimes happens that the loss of energy during the acceleration period outweighs the loss of converting to direct current.

ELECTRIC WINDERS ON WITWATERSRAND.

Name.	Depth in ft.	Tons (2,000 lbs.) per hour.	Weight of Mineral.	Weight of Skip.	Maximum Rope Speed.	Drum Diameter.	Winding Rope Diameter.	Tail Rope Diameter.	H.P.	System.

The last-named winder (Whiting hoist) shows an overall efficiency of 77 per cent.

(J. F. Perry, *Trans. Nat. Assoc. Col. Man.*, xv., p. 299.)

At the East Geduld Mines an electric winder hoists from a depth of 3,350 ft. 1,400 lbs. per wind, 230 (short) tons per hr.; drum cylindrical 14 ft. diameter, 5 ft. between flanges, maximum 3,580 speed ft. per min.: maximum peak capacity to be 4,570 h.p.

At Aberdare colliery, N.S.W., an electric winder raises 7½ tons net per wind, 490 tons per hr. from a depth of 1,260 ft.; it is rated at 4,500–11,250 h.p. Another shaft at this colliery has an electric winder making 133 trips per hour, with a net load of 4¼ tons, the maximum winding speed being 2,555 ft. per min.

An electric winder is used at Orient No. 2 mine at West Frankfort, Ill. (Chicago, Wilmington & Franklin Coal Co.). Coal skips normally weigh 10 tons, maximum weight, 11·5 tons; coal dumped at shaft bottom from mine cars by tipplers; depth of shaft, 202 yds.; normal output, 1,500 tons per hour; maximum, 2,000 tons per hour; time of wind, 16 secs.; maximum winding speed, 4,000 ft. per minute; peak load during acceleration, 8,000 h.p.; two motors, each 2,000 h.p. one placed at each end of drum shaft; motor generator set; 40 tons fly wheel, 12 ft. diameter; equipped with two 1,800 kW., 600 volt, 600 r.p.m., d.c. generators, driven by a 2,200 h.p. induction motor 220 volts, 3-phase, 60 cycles, 600 r.p.m. At the Nemacolin Mines, Pa., the seam is 250 ft. below and the tipping platform 90 ft. above ground level; the skip carries 16 tons and the plant can wind 1,500 tons per hour; the electric winder develops 1,400 h.p., the drum being cylindro-conical.

The largest electric winder in Gt. Britain is at the Carlton Main Colliery, Grimethorpe; it raises 300 tons per hour from a depth of 2,610 ft., and can develop 7,500 h.p. at 49·6 r.p.m.: it has a 23-ton flywheel Ilgner set.

For full information on electric winders see 'Electric Winders' by H. H. Broughton, 1927, and chapter on 'Electrical Winding in Colliery Machinery and its Application' by R. A. S. Redmayne, 1932.

Electric winders at British collieries have become far more numerous as the 'grid' system has developed.

Automatic control, often electric, is being used. Usually the control of the winding motor is effected by an oil-immersed quick make-and-break reversing switch in the static circuit and a liquid controller in the rotor circuit.

Headgears.

Headgears.—Steel-framed headgears usually range from ¾ to 1 ton per foot of height, and cost erected 12*l.* to 18*l.* per ton; headgears composed of angles and joists only, not lattice girders, weight ½ to ¾ ton per foot of height. Wooden headgears weight about ½ ton per foot of height and cost 10*l.* to 12*l.* per ton. The size of the main legs of timber headgears is given approximately by the expression $A = 0\cdot03\ H^2 \sqrt{W}$, where W is the total working load on the winding ropes in tons, H the height in feet of the headgear from the ground to the pulley centres, and A the area of the cross-section of the main leg; the area of the backstay $= 0\cdot64$ A.

(R. Boyle, *Scott. Inst. Min. Stud.* 1908.)

Steel headgears are now often welded and not riveted.

Ferro-concrete headgears have been erected in several places and have proved quite satisfactory.

Pulleys.

Pulleys.—Usually 10 to 20 ft. in diameter, mostly of the same diameter as the drum. The size depends more on the diameter of the wire used in making the rope than that of the rope itself—and should, according to one eminent authority, be from 1,000 to 1,400 diameters for iron and 2,000 to 2,100 for steel.

If F = the force in lbs. applied to the rim of the pulley required to overcome friction of axle.
W = weight in lbs. upon the axle of the pulley.
D = diameter of the pulley in inches.
d = diameter of axle in inches.
m = coefficient of friction, say 0·07.

$$\text{Then } F = \frac{Wmd}{D}$$

$$\text{or} \quad D = \frac{F}{Wmd}$$

Pillow blocks may be carried on strong springs to diminish shock at starting.

If W be the weight of a pulley in cwts. and d its diameter in ft., $W = 9\cdot2\,(d - 8)$ approximately for large colliery headgear pulleys. $W = \frac{d^2}{4}$ is a useful approximation, but is too low for pulleys under 6 ft. in diameter.

The angle of lead from the drum to the head pulleys should not exceed 2° on either side of the centre line; the horizontal distance between the drum and pulley centres should not exceed 150 ft., otherwise the rope is apt to surge.

Drainage of Mines.

MEASUREMENT OF WATER FEEDERS.

1. The meaaurement of the flow of water over a double notch weir, the upper portion of which is 12 ins. wide and 4 ins. deep and the lower 6 ins. wide and $4\frac{1}{2}$ ins. deep. The same formula is used in each case treating the weir in vertical sections.

$$Q = 3 \cdot 2\, l h^{\frac{3}{2}}$$

where Q = flow in cubic feet per second.
l = length of notch (or weir) in feet.
h = depth of water flowing over notch in feet.

2. Flow of water in pipes. $Q = 0 \cdot 62 a \sqrt{2gh}$

where V = velocity in feet per second.
g = acceleration due to gravity or $32 \cdot 2$.
h = height of head in feet.
a = area of orifice and $0 \cdot 62a$ is the coefficient for contraction (*vena contracta*).

3. The effect of friction is to reduce the pressure in the latter part of the tube or pipe below that which would exist if friction were absent.

$$\text{Loss of head} = 4f \times \frac{l}{d} \times \frac{V^2}{2g}$$

where l = length of pipe in feet.
d = diameter of the pipe in feet.
$f = 0 \cdot 0075$ approximately.

Drainage of Siphon.—Hawksley's rule for determining the flow of water through siphons is as follows :—

Let L = length of siphon in feet.
d = diameter of siphon in feet.
E = effective fall of siphon in feet.
W = velocity of flow in feet per second.

$$\text{Then V} = \left(\sqrt{d\frac{E}{L}}\right) \times 48.$$

Cornish pumps are never installed at mines now, and very few remain in existence. The foundations are massive and costly, as is the engine also, and the mechanism does not experience uniform strain or work at a uniform speed. Pumping engines are now mostly erected underground and force the water to the surface, but one form of surface-erected pumping engine, the Hathorn-Davey Differential Engine, is still in use as it meets all the disabilities of the Cornish Beam Engine, being a horizontal, reciprocating compound condensing engine which when placed at the surface works a double range of pump rods through the medium of a wooden connecting rod attached to a quadrant.

Other types of mine pumps which are placed below ground are the Tangye, Evans, Worthington, the Reidler, and centrifugal pumps worked electrically. Ram pumps work at speeds of 100 to 200 ft. per minute.

If n be number of complete strokes (i.e. up and down strokes) per min., and d the diameter of the ram or bucket, the theoretical discharge G in gallons per min. is given by $G = 0 \cdot 034 d^2 n.l.$ The actual discharge is less than this by the slip, which ranges from 3 per cent. to 30 per cent. in extreme cases. In practice it is usually between 10 per cent. and 15 per cent. It must be deducted from the theoretical discharge to get the actual discharge. Maximum velocity of water in rising main 200 to 300 ft. per min. rarely exceeds 100 ft. in small pumps; maximum velocity in windbore, 40 ft. per min.

Pressure at bottom of rising main = pressure due to static head + pressure required to overcome resistance of pipe.

If v be the velocity of discharge in feet per second, H the vertical head in feet, L the length in feet of the pipe, D its diameter in inches, and P the total pressure at bottom of rising main, then,

$$P = 0 \cdot 341\, D^2 \left(H + 0 \cdot 024 \left(\frac{L}{12D}\right)^{4} \frac{v^2}{2g}\right).$$

* Printed and published by H.M. Stationery Office. Price 1*s.* net; 1*s.* 2*d.* post free.

The pressure in the steam cylinder must be capable of overcoming this pressure, allowing for the mechanical efficiency of the engine (say 0·66).

The content of a pipe in gallons of water = $0{\cdot}034\ D^2L$.

The thickness of a pipe can be calculated thus :—

Thickness in inches = 0·000125 P.D. + 0·5.

Thickness of pump-barrel = $0{\cdot}5 + \frac{P.D.}{2{,}000}$, where P is pressure in lbs. per sq. in.

Weight of pipe in lbs. = $2{\cdot}5\ L\ (D^2 - d^2)$, where D and d are external and internal diameters. The flange = weight of 1 ft. of pipe.

Horse-power in the water lifted = $\frac{g\ H}{3{,}300}$, where g is the actual delivery in gallons per min.

The 'duty' of a Cornish pumping engine is the number of millions of pounds of water lifted one foot high by the consumption of 112 lbs. of coal (before 1856 of one bushel=94 lbs., and in America of 100 lbs. of coal) under the boilers. To convert duty into lbs. of coal burnt per h.p. in the water, divide 222 by the duty. It is always theoretical discharge that is taken in calculating duty. Cornish engines have worked with as little as 1·5 lb. coal per h.p.; 2·5 to 3 lbs. is a usual figure.

For double-acting pumps the formula for discharge previously given becomes

$$G = 0{\cdot}068\ d^2 n.l.$$

If A be the area of the piston, n number of strokes per minute, S length of stroke, b the height of the water barometer, l the length of the windbore, a its area, h the vertical height of the suction lift, g the acceleration of gravity,

$$a > 0{\cdot}0055\ \frac{An^2 Sl}{g(b-h)} \text{ for single-acting pumps, and } > 0{\cdot}00275\ \frac{An^2 Sl}{g(b-h)} \text{ for double-acting pumps.}$$

or the piston will rise faster than the water can follow it, and hammering will result.

The air-vessel should have a volume = 4 times that of barrel for single-acting, and 1·6 times for double-acting pumps. *(Weisbach.)*

The most economic diameter of a rising main can be calculated by the method given in *Trans Inst. Min. Eng.*, vol. lxxvii., p. 75.

Centrifugal Pumps.

These are the types of pumps now chiefly employed in the drainage of mines.

(See *Trans. Inst. Min. Eng.*, vol. lxxxviii., p. 9.)

Let u be peripheral velocity of impeller in ft. per sec.

- r radius of the impeller in feet.
- n number of revolutions per second.
- d depth of openings in impeller in feet.
- i number of impellers in series.
- h height of total lift in feet.

then

$u = 2\,n\,\pi\,r$. Velocity of radial water discharge from impeller = K u, where K is a coefficient between 0·1 and 0·3, averaging 0·2. Quantity of water discharged per second = $K\,u\,2\,\pi\,r\,d = 4\,K\,n\,\pi^2 r^2 d$ cub. ft. $h = c\,\frac{i\,u^2}{2g}$, where c is a coefficient that varies considerably, but is mostly between 0·75 and 1.

Mechanical efficiency (m) is between 0·5 and 0·8, usually about 0·7.

Hence h.p. required = $\frac{8\,K\,c\,\pi^4 n^3 r^4\,i\,d}{8{\cdot}8\,m\,g}$, or, taking average values, h.p. = about $\frac{3}{4}\,n^3 r^4\,i\,d$.

Direct coupled motor-driven centrifugal pumps to pump 1,500 gallons p.m. to a height of 1,000 ft. have been found to have an overall efficiency of 71·6 per cent.; electrically driven ram pumps would have an overall efficiency of 80 per cent. *(Prest & Leggat.)*

(See also p. 810, Vol. I.)

VENTILATION.

Mine Gases and Ventilation.

Pure dry air according to Haldane consists by volume of:—

Oxygen	20·93 per cent.
Nitrogen	78·10 „
Argon	0·94 „
Carbonic acid	0·03 „
	100·00 „

With 17·0 vol. a candle is extinguished, but breathing is still possible; with 15·2 vols. of oxygen breathing becomes more difficult; with 10 vols. of oxygen, very difficult; and with 5 or 6 vols. practically impossible. Each person requires ordinarily when at work 20 cubic feet of air per min., or when in a working place giving off ½ per cent. of gas 40 cubic feet per min. Each horse requires 90 cubic feet per min. and each flame safety lamp ⅛ cubic foot per min.

Approximately in Great Britain 5·8 tons of air pass through coal mines per ton of coal raised.

The blood in a man's body is capable of absorbing about one pint (about 20 per cent. of its volume) of either oxygen or carbonic oxide when saturated. If it be half saturated with carbonic oxide, unconsciousness sets in, and with higher proportions death follows. In air containing 0·1 per cent. of carbonic oxide the blood would become half saturated in about an hour in the case of a man at rest, and in about half an hour in the case of a man taking exercise. Anything above 0·15 per cent. of carbonic oxide must be considered dangerous; 0·16 per cent. will cause slight distress to mice in an hour, 0·2 per cent. distress in 8 minutes, 0·3 per cent. distress in 4 minutes, 0·45 per cent. distress in 2 minutes and collapse in 4 minutes, 0·57 per cent. distress in 1 minute, collapse in 6½ minutes, and death in 12½ minutes. With canaries 0·09 per cent. causes distress in one hour, 0·15 per cent. distress in 3 minutes, fall from perch in 18 minutes, 0·2 per cent. distress in 1½ minutes, fall from perch in 5 minutes, and 0·3 per cent. fall from perch in 2½ minutes.

Fire-damp.—Fire-damp consists essentially of marsh gas or methane, CH_4, the remainder consisting of nitrogen and carbonic acid; hydrogen and some of the higher hydrocarbons have also been found in some samples. Haller and Moureu have found helium with traces of neon (0·003–0·05 per cent.), and argon with traces of krypton and xenon (0·003–0·04 per cent.) in fire-damp. The high explosive range of a mixture of methane gas and air is with mixtures containing 8 to 14 of methane; when present to the extent of 22 per cent. methane the mixture is non-explosive, the lower limit of inflammability is 6·1 per cent. methane. The igniting point is between 650° and 750° C., and there is always a perceptible 'lag' or delay in the ignition, the amount of which depends upon the temperature. According to Taffanel and Le Floch, mixtures containing only 3 per cent. of marsh gas will ignite at 680° C. and as much as 30 per cent. at 875°. In a mixture of 6·5 per cent. of marsh gas with air, quantity of gas burnt per second varies from 0·00075 per cent. at 535° C. to 0·05 per cent. at 640° C. According to H. Le Chatelier the igniting point of acetylene is 450° C., hydrogen 550° C., methane and carbonic oxide 650° C. The velocity of propagation of ignition of methane ranges from 0·03 m. per sec. with 6 per cent. of methane to a maximum of 0·61 m. per sec. with 12 per cent., and falls again to 0·1 m. per sec. with 16 per cent. of methane in air. The velocity of the explosive wave in a mixture of methane with pure oxygen is 2,500 m. per sec. Marsh gas has been given off in quantities up to 4,500 cubic feet per ton of coal wrought, and has been shown to exist in coal under pressure up to 40 atmospheres. It is on record that in one mine as much as four million cubic feet of fire-damp has been given off in 24 hours.*

Experiments on the ignition of mixtures of methane and air by electric sparks have been recorded by Dr. Thornton (*Trans. Inst. Min. Eng.*, xliv. p. 145, and xlvi. p. 112). Dr. Wheeler found in experiments carried out at the instigation of Sir R. Redmayne in 1914 that with 3 Dania cells giving a current (on closed circuit) of 0·45 amps. under a pressure (on open circuit) of 4·5 volts it is possible to produce a spark by short circuiting the current in signal wires to give a signal, which will explode a mixture of air and methane when methane is present to the extent of 8·2 per cent.

It has been shown that mixtures of methane and air can be ignited by the impact of siliceous rocks on each other. (Safety in Mines Research Board, Paper No. 46.)

Firedamp Detectors.

Coal Mines.

On May 1, 1935, the Board of Trade issued an order that in every ventilating district in which safety lamps are required, a sufficient number of appliances, approved by the Board of Trade, for detecting the presence in the air of inflammable gas, shall be provided by the owner of the mine for use by the workmen employed. In general the number of detectors to be provided for use shall not be less than in the proportion of one detector, in longwall workings for every eight, and in other workings every four, of the total number of persons who are wholly or mainly employed at the working faces.

* See *Trans. Inst. Min. Eng.*, vol. lxxxviii., p. 120.

The provisions for the examination of safety lamps shall apply to these detectors.

In place of the safety lamp required in certain circumstances for use with electric motors General Regulations, 1913), a detector may be provided and used.

These Regulations came into force on October 1, 1935, and may be cited as the Coal Mines General Regulations (Firedamp Detectors), 1935.

The 'Ringrose' is the only approved 'automatic' detector.

PRINCIPLES OF VENTILATION.

(See 'The Ventilation of Mines,' by Hy. Briggs, 1928 'Ventilation of Mines,' by R. A. S. Redmayne; also *Trans. Inst. Min. Eng.*, vol. lxxxviii., p. 109.)

The difference of pressure producing ventilating currents in mines is measured by the water gauge; a column of 1 in. of water corresponds to about 66 ft. of air at 60° F. and 30 ins. of barometric pressure. The theoretical velocity of air due to such pressure is given by the expression $v = 66\sqrt{h}$, where v is the velocity in feet per second and h the water-gauge in inches. If the friction in the airways of a mine is taken into account, according to Murgue—

$$h = K\frac{l\,p\,v^2}{a} \text{ or } h = K\frac{l\,p\,Q^2}{a^3}$$

where l is the length of the air passage, p its perimeter, a its area, all in feet, and Q the quantity of air in cubic feet per second. Values of coefficient K: for drifts, bricked and arched, K = 0·0000012; in ordinary rock, untimbered, K = 0·0000034: timbered in the usual way, dimensions taken inside timbers, K = 0·0000057. If the quantities and velocities be given in thousands of feet per minute, these coefficients become 0·00033, 0·00094 and 0·00156 respectively; some engineers use Mr. Fairley's coefficient, which is 0·002. The critical velocity of air flowing in circular pipes $= \frac{18}{D}$ feet per min., where D is the diameter of the pipe in feet.

The work required to move a quantity Q of air under a water-gauge of h inches = 5·2 hQ foot-pounds.

Mr. J. T. Storrow has found that the quantity of air flowing through material under 0·25 in. in size at a slow rate varies directly with the pressure and not with the square root.

(*Trans. Inst. Min. Eng.*, lv. 313.)

The loss by scaling through packwalls, etc., would therefore, for the same difference in pressure, be greater than in an open airway.

Measurement of flow of air.—In a pipe circular in section a velocity equal to the mean flow is at 0·15 of radius from the wall of the pipe. In a mine drift the mean of two measurements halfway between roof and floor and one-sixth of the width of the airway from either side will approximate to the mean velocity of the air in the drift. The mean velocity is between 0·7 and 0·85 of the maximum velocity at the centre of the drift, averaging 0·78.

If the pressure of air on either side of a regulator or other diaphragm with an aperture of e square feet be determined by water-gauge, and the difference of gauge pressure be d inches, the quantity of air flowing is 40 $a\sqrt{d}$ cubic feet.

The anemometer is used generally for measuring the velocity of the air current, but the Pilot tube may be adopted in cases where high accuracy is desirable when for practicable purposes the velocity may be calculated from the formula:—

$$V = 1098\sqrt{\frac{WG}{W}}.$$

where V = velocity in feet per min.
W.G. = velocity pressure in ins. of water gauge.
w = weight in lb. of 1 cubic feet of air flowing.

Where the measurement of low velocities is necessary the Kata thermometer is sometimes used, especially in the South African Gold Mines.*

In order that the rate of heat loss may be expressed in heat units the total heat loss while cooling between the marks 100° and 95° F. (or corresponding Centigrade) is determined for each instrument by the number of marks and is divided by the surface area of the Kata expressed in sq. cm. The heat unit being a mille calorie ($\frac{1}{1000}$ of 1 grm. calorie). The mean time of cooling of the Kata having been obtained, the factor number is divided by this, and the result is the rate of heat loss per sq. cm. of bulb per second, or cooling power H. To determine air velocity the temperature of the air θ is also taken, then

$$\frac{H}{\theta} = \frac{\text{cooling power}}{36\cdot5 - \text{air temperature, °C}}$$

From this observed value for $\frac{H}{\theta}$ the velocity of air movement can be obtained in cm. per second.

Ventilation surveys are being used increasingly.†

* See 'The Measurement of Low Air Velocities in Mines,' J. P. Rees, *Trans. Inst. Min. Eng.*, vol. lxxiv., 1927–28, p. 359.

† See *Trans. Inst. Min. Eng.*, vol. lxxxviii., p. 181.

Natural Ventilation and Furnace Ventilation.

Natural Ventilation and Furnace Ventilation.—If there be two shafts, the mean temperature of the air in each of which is respectively T and t (in degrees Fahrenheit), the water-gauge due to this difference of temperature will be $\frac{H}{66}\left(\frac{T-t}{459+T}\right)$, where H is the depth of the pit in feet, assuming that the temperature of the atmosphere is 60° and the pressure 30 ins., under which conditions a cubic foot of air weighs 0·0765 lb.; under any barometic pressure of β inches and temperature $t°$ Fahrenheit, the weight of a cubic foot of air is $\frac{1\cdot326\ \beta}{459+t}$, by means of which formula the necessary correction can be applied. The number of heat units required to produce the above water gauge will be $\frac{1\cdot326\ Q\ \beta\ (T-t)}{459+t} \times 0\cdot2375 = \frac{0\cdot315\ Q\ \beta\ (T-t)}{459+t}$ heat units per second.

The grate area is often taken $= \frac{34}{\sqrt{H}} \times \frac{5\cdot2\ hQ}{550}$ sq. ft.

In practice, to pass 300,000 cubic feet of air per min. with a 2-in. water-gauge about one ton of coal is burnt per hour.

Ventilation of coal mines by furnace in Great Britain is permissible only in the case of a small mine, i.e., in which the total number of persons employed below ground does not exceed 30 or if the mine was opened out prior to the year 1911; very few mines now use it.

There is a limit to the efficiency of furnace ventilation, because of the expansion of the air in the shaft due to heat and increasing velocity augments the frictional resistance. Pectet thus stated that when the upcast air has expanded to twice its original volume, the limit of furnace ventilation has been attained. Theoretically about 150 cubic feet of air are necessary for the combustion of 1 lb. of average coal. In practice, however, it takes about twice this amount of air. In the case of an extensive colliery ventilated by furnace which caused 271,356 cubic feet of air to pass down the downcast shaft, the power of the furnace was equal to 111 h.p., but this must be regarded as an extraordinary case.

Fan Ventilation.*

(See Reports of the Institution of Mining Engineers on Mine Ventilation, *Trans. Inst. Min. Eng.*, vol. lxvii., pp. 268, 273; vol. lxx., p. 162; vol. lxxi., p. 337; vol. lxxiii., p. 78; vol. lxxvii., p. 188; vol. lxxxi., p. 313; vol. lxxxvii., p. 9.)

Centrifugal Fan.—If u be the peripheral velocity of the fan blades in feet per second, the theoretical water-gauge produced $= \frac{u^2}{68g} = \frac{u^2}{2180}$.

The manometrical efficiency of a fan ranges from about 0·45 for an open-running fan up to about 0·9 for a good modern enclosed fan.

The volumetric efficiency under given conditions is the volume of air actually passed by the fan divided by the volume of the fan × number of revolutions.

The mechanical efficiency is the horse-power required to drive the fan (or of the fan and fan-engine, as the case may be) divided by the horse-power in the quantity of air moved $= \frac{5\cdot2\ hQ}{550}$. It varies from about 45 to about 75 per cent. in different types of fans.

The equivalent orifice of a mine $o = 0\cdot4\ \frac{q}{\sqrt{h}}$, where q represents the quantity of air in thousands of feet per minute, and o the area in sq. ft. The equivalent orifice of British mines is usually between 20 and 30 sq. ft.

If H be the initial water-gauge of a given fan (maximum water-gauge, produced on exhausting out of a closed vessel), the equivalent orifice of a fan, working on a mine with equivalent orifice o, should be $= o\sqrt{\frac{h}{H-h}}$. The inlet area of a fan should be about 20 per cent. greater than its equivalent orifice. The equivalent orifice of a fan should be about three times that of the mine on which it works. The velocity at which air enters the fan orifice should be between 1,000 and 1,500 ft. per min. If k be the manometric efficiency of any fan, according to Murgue—

$$u = \sqrt{\frac{g\,68\,h}{k}}.$$

To find the horse-power of a motor or engine required to drive a fan under average mine conditions, multiply the number of cubic feet of air by the water-gauge and divide this product

* See Report of the Fan Standardisation Committee of the Inst. of Heat and Ventil. Eng., June 1927; also Min Inst. Report on Testing of Mine Fans, *Trans. Inst. Min. Eng.*, vol. lxxxviii., p. 170; also Mine Ventilation, a Review of Present Theory and Practice by R. Clive, W. Hay and I. G. F. Statham. Tenth Report of the Midland Institute Committee on the Ventilation of Mines.

by 4,500. Example: If a fan is delivering 100,000 cub. ft. of air at 2-in. water-gauge, what should be the horse-power of the motor or engine required to drive it?

$$\text{H.P.} = \frac{100{,}000 \times 2}{4{,}500} = 44 \cdot 4. \qquad (\textit{Machinery.})$$

The Steart fan is an air-screw or propeller fan which is stated to give a very high efficiency and to be readily adaptable to the changing conditions of a colliery. See *Journ. Chem. Met. and Min. Soc. So. Afr.*, vol. xxiv., 1923, p. 31; *Trans. Inst. Min. Eng.*, vol. lxviii., 1924–5, p. 310.

The Report of the Technical Advisory Committee (the Reid Report of March 1945) recommends the wider use of axial-flow type of fans in British coal mines.

Axial-flow fans with variable pitch propellers are now being supplied to collieries and mines in this country and abroad. One of the standard fans made by Walker Bros. (Wigan), Ltd., has a capacity of 250,000 cub. ft. per min. at 6-in. water gauge.

REGULATORS.

Regulators.—If A be the area in sq. ft. of a regulator which is required to produce as much resistance to the flow of air as a roadway of length l, perimeter p, both in feet, a area in sq. ft., K = Murgue's coefficient of friction as above when the quantity of air is expressed in thousands of cubic feet per minute and the pressure in inches of water-gauge, then $A = 0 \cdot 4 \sqrt{\frac{a^3}{Kpl}}$. The regulator should be placed behind the last man in the split.

Safety Lamps.

Until recently it was held that a lamp gauze should be of wire $\frac{1}{70}$ in. diameter and contain 28 meshes to the linear in. (784 meshes per sq. in.); recent researches by the Miners' Lamps Committee have resulted in recommending wire $\frac{1}{50}$ in. diameter with 20 meshes to the linear in. (400 meshes per sq. in.).

See 'Mine Lighting,' by J. W. Whitaker, 1928.

The Technical Advisory Committee in the Report (Reid Report, March 1945) regard the present standard of underground lighting at British collieries as being too low, and consider that a standard of the order of 0·4 ft.-candles in the general working area should be aimed at, that as a source of illumination the flame safety-lamp is obsolete, that a system of general lighting by power-fed lights supplemented, preferably by cap lamps, is necessary at the coal face.

Lamps burning benzine of sp. gr. 0·765, costing 1*s.* per gallon, gave the following results :—

	Candle-power.		Cost in pence per 1,000 lamps of one average c.p. hour.
	At Beginning.	At End.	
Wolf	0·99	0·94	16¼
Protector . . .	0·72	0·66	25¼

Flood lighting at the colliery face is advocated by several authorities. (See *Trans. Inst. Min. Eng.*, vol. lxxxiv.)

Portable Electric Lamps.

It is considered that the ultimate improvement of mine lighting required involves the adoption of mains lighting throughout the pit. However, even in this event, a certain number of portable lamps will still be used, and during the period of years needed in the development of mains lighting, portable lamps will still constitute the chief supply of illumination.

The problem, in the case of portable lamps, is to provide increased lighting without excessive weight, bearing in mind the fact that increased wattage requires a larger battery to feed it throughout the working shift.

A cap-lamp throws the entire light forward in the direction that the wearer is normally looking, and for the same power gives about three times the light in the area of the beam as would an ordinary hand-lamp. However, the general contribution to illumination at the face is no greater.

Bulbs filled with krypton gas give 20 per cent. more light than argon-filled bulbs for the same power consumption. Likewise reduction in the specified life of bulbs would make for greater output of light.

Fluorescent Lighting.

Fluorescent Lighting underground on roadways and at the face is a development on which a number of experiments have been made.

Some of the advantages over filament lamps are the greater efficiency, longer life, and with the much larger area from which light is emitted, the consequently reduced glare—a specially important feature considering the low mounting height possible in a mine. The undesirable sharp shadow effect is also eliminated.

Fluorescent lighting, however, is not intrinsically safe since there is a slight possibility of ignition in gassy mines in case of breakage of the glass tube, though the danger is far less than with filament lamps. Likewise the chances of short life caused by vibration are much smaller, since the starter filaments at each end of the fluorescent tube are very small compared with the filament in an ordinary lamp of the same power.

Nevertheless, regarding replacements and maintenance in general, together with the refitting of lights at the face as it moves forward, there are still a great number of drawbacks to overcome.

See 'Fluorescent Lighting Underground in Mines,' by F. Widnall, *T.I.M.E.*, vol. cvi., pp. 593–605.

Gas Caps.

***Gas caps* are shown in an ordinary safety lamp with the flame turned down so as just not to show any white light, when introduced into an atmosphere containing small amounts of marsh gas or methane, approximately as follows :—**

2 % of marsh gas. Cap ½ in., just visible except at extreme tip.	4½% of marsh gas. Cap 1½ in., well defined.
3 % " " " ½ in., fully formed.	5 % " " " 2½ ins. " "
4 % " " " ¾ in., well defined	5½% " " " 4 ins. " "
	6 % " " " fills the safety lamp.

Gas-testing lamps burning alcohol will show clearly as little as 0·2 per cent. of marsh gas.

Coal Dust.

(See 'The Collection and Analysis of Air-borne Dust during the Driving of Hard Headings,' by J. Ivon Graham and F. Lawrence, *Trans. Inst. Min. Eng.*, vol. xcii., p. 1.)

Coal-dust.—Three ounces of coal-dust per cubic yard of gallery space is sufficient to produce an explosive mixture; excess of coal-dust prevents neither the initiation nor the propagation of an explosion. Coal-dust giving less than 12 per cent. of volatile matter is practically incapable of initiating an explosion. At least 50 per cent. of inert stone-dust is required to prevent the initiation of an explosion. If less than 75 per cent. of the dust passes the 200 sieve it is difficult to initiate an explosion. (*Abstracted from the Lieven experiments.*)

The temperature of ignition of coal-dust is about 1,000° C. Mixed with air and introduced into a heated vessel the temperature may be as low as 590°; there is very little lag. (*Taffanel and Le Floch.*)

The General Regulations provide that in all coal mines except anthracite mines, the mine roadways shall be so treated with incombustible stone dust that contains a percentage of incombustible matter to the extent of 65 per cent. (incombustible matter includes moisture). The incombustible dust used for dusting the mine shall be of such a fineness that of the dry dust which passes through a 60 mesh sieve not less than 50 per cent. by weight, and not more than 75 per cent. by weight shall pass through a 240 mesh sieve and shall be of such a character that it is readily dispersable into the air. Representative tests must be made by the management at intervals of not less than one month, and the results posted at the pit head. The method in which the tests are to be made is fully prescribed by the Statutory Orders (see those issued December 8, 1939). Samples of the dust must be systematically collected and analysed and, in respect of roads used for the transport of coal, and of return airway within 200 yds. of the working face, the number of such samples during each calendar month shall not be fewer than in the proportion of ten per mile of those roads and airways.

In any seam in which, however, inflammable gas is unknown and in which no explosive other than a sheathed permitted explosive is used in any road or ripping or any dry and dusty part of the mine, the percentage of incombustible matter shall not be required to be more than 50 per cent., if that is the natural condition of the dust throughout the road, or more than 60 per cent. if the road is treated with incombustible dust.

Rescue Apparatus.*

Rescue apparatus may be divided into three classes:—

(1) Respirators, which do not supply oxygen, and which absorb by means of a chemical, specific noxious gases.

(2) Tube apparatus, in which the wearer is supplied with fresh air through a tube by means of a bellows or fan.

(3) Self-contained breathing apparatus in which the wearer carried all the means of supporting respiration over a period of two hours independent of any other person or persons.

Respirators are not approved for use in mines by the British Mines Department, although the American Bureau of Mines have approved of their use in U.S.A.

Tube apparatus of the smoke helmet and equaliser types are now approved for use in mines in this country, and there must be maintained at each mine with over 100 underground employees, one of such type of appliance ready for use. The length of tubing employed is 120 ft.

Self-contained breathing apparatus are of two main types depending on the nature of the oxygen supply.

(1) Where the oxygen is carried in steel cylinders at a pressure of 120 atmospheres.

(2) Where the oxygen is carried in the form of liquid air, the liquid occupying one eight-hundredth part of its gaseous equivalent.

The weight of this class of apparatus ranges from 36 to 40 lbs. The expired carbon dioxide is absorbed by from 2 to 4 lbs. of granulated caustic soda, and in a few cases specially prepared soda lime is used.

According to the Rescue Regulations, C.M.A. 1911, the supply of oxygen to the wearer must not be less than two litres of oxygen per minute.

The chief types in use of this class are:—

Great Britain.—Proto: Siebe, Gorman & Co., Ltd., London. Aerophor: Guest & Chrimes, Ltd., Rotherham.

* Kindly supplied by F. P. Mills, Chief Officer, the Durham and Northumberland Collieries Fire and Rescue Brigade.

America.—Gibbs: Mines Safety Appliances, Pittsburg, U.S.A. McCaa: Mines Safety Appliances, Pittsburg, U.S.A.

Germany.—Draeger: Draegerwerke, Lübeck, Germany.

To Detect Carbon Monoxide in the Air.—The most satisfactory and practical method of detecting CO is by means of a small bird. The bird is affected from 7 to 10 times quicker than man, and gives ample warning by its behaviour.

Numerous chemical devices have been evolved for this purpose but none has been adopted for general use in mines.

For accurate quantitative estimations there is perhaps no more satisfactory method than that suggested by Haldane (*Journ. of Physiology*, vol. xviii. p. 430). This is a colorometric test and depends on the colour of blood which has been exposed to the CO under test, relative to that of an equal amount of blood fully saturated with the gas, the matching of the former to the colour tint of the latter being effected by a standard solution of carmine. The spectroscopic test of blood which has been saturated with the suspected gas for the spectrum of carboxy-hæmoglobin is a very simple and rapid qualitative test (*Gas Poisoning in Mining and Other Industries*, p. 381). (*Glaister & Logan.*)

It is estimated that 120 cubic inches of oxygen per min. is ample for the severest exercise; a man at rest requires about 15 inches, and climbing hills 90 cubic inches per min.

The following has been found to be a man's average consumption of oxygen per minute, gas dry, at N.T.P.

Rate of doing Work.	Breathing.			
	Air.		Oxygen.	
	Litres.	Cub. in.	Litres.	Cub. in.
At rest	0·36	22	0·32	19·5
3,000 ft.-lbs. per min. . .	1·12	68·3	0·97	59·2
6,000 " "	1·74	106·2	1·54	95
9,000 " "	2·33	142·2	2·16	131·8

The most economical rate of walking when travelling a flat road and wearing a rescue apparatus—*i.e.* the rate at which a maximum distance can be covered for a given supply of oxygen —is about 2½ miles per hour.

(' *Second Report of the Mine Rescue Research Committee of the Department of Scientific and Industrial Research* ')

When the wet-bulb temperature is much above 80°F., a man cannot remain long at work; he can stand a wet-bulb temperature of 120°F. for about five minutes. (*J. S. Haldane.*)

Recently the 'Hoolamite' detector has been used. This consists of iodine pentoxide dissolved in fuming sulphuric acid, the changes of colour in which indicate the amount of carbonic oxide present; it is said to be able to detect 0·07 per cent. A carbonic-oxide recorder has also been developed, which works by recording the rise in temperature in 'Hopcalite.' This consists of a catalyst combined with oxide of manganese which oxidises carbonic oxide to carbonic acid; the heat developed by this reaction is a measure of the amount of carbonic oxide oxidised. (See 'Devices for Detecting Dangerous Gases in Mine Air,' by J. T. Ryan. '*Trans. Amer. Inst. Min. Met. Eng.*' vol. lxxv., p. 599.) Mr. Ivon Graham has shown that carbon monoxide is a normal constituent of the air of coal mines over 1,500 ft. deep, being produced by the slow oxidation of carbonaceous material at the coal face, in the roads, and in the goaf; it is usually under 0·005 per cent., but in a few cases 0·012 per cent. has been found.

('*Trans. Inst. Min. Eng.*,' vol. lix., p. 222.)

Spontaneous Combustion.

See also Appendix A and B Final Report of the Committee on Spontaneous Combustion of Coal in Mines, 1921, H.M. Stationery Office.

Work in the Doncaster Coal Owners' Laboratory has shown that the liability of a coal to spontaneous combustion in the goaf depends, other things being equal, upon its capacity for absorbing oxygen. It appears that a coal, 100 grammes of which, ground to 200 mesh, absorb less than 200 c.c. in 96 hours at 30°C., is only liable to gob fires when the working conditions especially favour the latter. Coals liable to fire absorb over 300 c.c. in the same time. Presence of FeS_2, especially when finely divided, increases the liability to spontaneous combustion.

Pneumatic stowing, by reducing air leakage across the wastes, is a satisfactory preventative measure against spontaneous combustion.

Fire Extinction.

Investigations have been made into the scientific side of the mud-jet method of fire extinction in colliery workings, and it has been decided that the material of the mud, some of which should be of a lime and some of a clay character, should consist of sifted earth of 5 mm. mesh, boiler ash, dust from the cleaning of blast-furnace gas, and even combustible material, such as the refuse of coal washing, can be added to make up bulk without any risk should nothing more suitable be at hand. In the majority of instances the mud tank can be so placed as to operate by gravity, but steam or compressed air pressure can be used. It has been found that if a tank is placed at a height of, say, 15 yards, it will force the mud a horizontal distance of 150 yards, even allowing for fairly sharp bends in the conducting pipes. (See also Safety in Mines Research Board papers, Nos. 75 and 76.)

Electric Signalling in Coal Mines.

In British coal mines bells and relays have to be such as will not 'spark' (see General Regulation 132). It has been ascertained that with the type of bell and magnitude of battery which used to be employed in mines, nearly every break-flash that occurred when the bare signal wires were separated would ignite a mixture of fire-damp and air containing between 7·5 and 9·5 per cent. fire-damp, were such a mixture to surround the wires at the time.

The Report of the Advisory Technical Committee to the Ministry of Fuel and Power (1945), draws attention to the fact that in this country signalling systems have been developed chiefly to meet the needs of rope haulage and add that the efficiency of some leaves much to be desired, and points particularly to the bare-wire system which demands a high standard of maintenance. The enclosed, or insulated, system requires less maintenance and reduces delays, but necessitates the provision of contact makers at each signalling point and does not furnish the same measure of control throughout as the bare-wire system, although this may be overcome by providing pull-wire control between successive contact makers. This system has, the Report states, been developed especially for use with man-riding haulages.

The introduction of locomotive haulage—the Report proceeds—requires a different system of signalling, essentially based upon visual signals in conjunction with a suitable telephone system, affording communication between haulage junctions.

Signalling.—By the Regulations issued by the Ministry of Fuel and Power, where electricity is used for signalling the pressure in any one circuit must not exceed 25 volts, and contact makers shall be so constructed as to prevent the accidental closing of the circuit; and adequate precautions shall be taken to prevent signal and telephone wires from touching cables and other apparatus. In a seam or part of a seam in which safety lamps are required to be used, if any part of a circuit containing electrical apparatus is in use for signalling (other than apparatus used solely to control the raising and lowering of cages in shafts), it must be of a type approved by the Minister of Fuel and Power. The apparatus has to be constructed so as to conform in all respects with the certificate and with the drawings and specifications appended thereto.

The source of current to be used for operating the apparatus shall be :—

(*a*) For direct current signalling, a battery of 3-pint porous-pot Leclanché cells connected in simple series, or such other source of current as may be certified for the purpose by the Minister of Fuel and Power.

(*b*) For alternate current signalling a transformer of a type certified for the purpose by the Minister of Fuel and Power.

(*c*) For magneto-call telephones, the generator included in the certified apparatus.

The circuits comprising apparatus must be arranged so that—

(*a*) No part of the circuit is connected to earth.

(*b*) Circuits supplied with current from different sources are not interconnected except that it is permissible to use the same line wires for the calling and speaking circuits of telephones.

(*c*) Direct current bells or relays when connected in parallel must be supplied from a single source of current.

(*d*) Direct current bells or relays when connected in series are to be supplied either from a single source of current, or from two identical of current connected in opposition.

(*e*) Magneto-call telephones have to be connected in parallel.

(*f*) Where magneto-call telephones of different types are connected in the same circuit, each instrument has to include a condenser of the type certified for the purpose and connected in shunt with the calling bell.

A list of approved types of signalling apparatus and telephones is issued by the Ministry of Fuel and Power.

ORE DRESSING AND COAL CLEANING.

(For details see 'The Dressing of Minerals,' by Henry Louis, from which the following is mainly abstracted.)

The operations included under the head of dressing comprise all the operations between the extraction or the crude mineral from the mine and rendering it merchantable, thus forming a link between the operations of the miner and the metallurgist. By common consent, gold milling is

generally looked upon as a dressing operation, though it is doubtful whether cyanidation should also be included.

The various operations consist of :—

Hand picking or sorting.

Comminution (coarse breaking or crushing and fine breaking or grinding).

Sizing (preliminary or rough sizing and final or fine sizing).

Classifying.

Separation by differences of specific gravity, magnetism, electric conductivity, or surface tension.

Usually a more or less complicated series of operations is required, especially in the case of complex ores, and these are usually indicated by means of flow sheets.

Let the weight of feed in any concentration process be A and its assay a per cent., the weight and assay of concentrates be B and b and of tails C and c respectively, then the

$$\text{Enrichment ratio} = \frac{b}{a} = \frac{\%\ \text{Recovery}}{\%\ \text{Concentration}}.$$

$$\%\ \text{Concentration} = \frac{100\text{B}}{\text{A}} = \frac{100(a-c)}{b-c}.$$

$$\%\ \text{Recovery} = \frac{100b(a-c)}{a(b-c)} = \frac{\text{B}100b}{\text{A}a}.\quad \text{A} = \frac{\text{B}(b-c)}{a-c}.$$

$$\%\ \text{Efficiency of concentration} = 100\frac{\text{B}}{\text{A}}\left(\frac{b}{a} - \frac{100-b}{100-a}\right) = 100\frac{a-c}{b-c}\left(\frac{b}{a} - \frac{100-b}{100-a}\right) =$$

$$100\ \frac{\%\ \text{Recovery} - \%\ \text{Concentration}}{\%\ \text{Waste in feed}}.$$

(*R. T. Hancock.*)

Sorting is performed either on floors or on picking belts or tables. An ordinary coal picking belt may be of iron plates 4 ft. wide, 50 to 100 ft. long, travelling at 40 to 65 ft. per minute. Pickers stand on both sides, 7 ft. to 15 ft. apart; each picker can treat 1–3 tons of coals per hour.

Power required to drive, 2½ to 5 h.p. Upkeep, about 50*l.* per annum.

Rubber-covered canvas belts about 32 ins. wide are also used, and will carry 25 to 50 tons per hour at speeds of 30 to 60 ft. per minute. Thin steel bands (Swedish) have also been used.

Circular tables are 3 to 4 ft. wide, 10 ft. to 18 ft. in diameter, revolving with a peripheral speed of 40 to 60 ft. per minute, and can deal with 30 to 70 tons of mineral per hour.

Comminution.—Rough breaking is done by jaw breakers, either reciprocating like those of the Blake, Dodge, etc., type, or gyrating like the Gates type. The former have been built to take pieces up to 5 ft. by 7 ft., requiring 300 h.p. to drive, and breaking 300 tons per hour. Smaller breakers usually break 1 ton per hour for a consumption of 2–3 h.p. The gyrating crusher is better suited to very large outputs, but cannot take such large pieces, and appears to be rather more economical of power.

Fine Crushing.—Rolls are used for medium and fine crushing. Let r be the radius of the particle to be broken and d the radius of the particles in the crushed product (both considered as spheres); the minimum radius of the roll should be $> 25\ (r - d)$.

For fine crushing to about ⅛-in. mesh the following table shows the general practice :—

Rolls.		Revs. per minute.	Horse-power required.	Cwts. crushed per hour.
Diam.	Face.			
10½ ins.	10½ ins.	130	3	25
12½ ,,	10½ ,,	110	4½	45
16 ,,	10½ ,,	90	6½	65
21 ,,	10½ ,,	75	9½	100
27 ,,	11 ,,	45	12½	145
37 ,,	12 ,,	45	16	200

The peripheral speed should be greater the finer the product required; for grinding to 40 mesh the speed should be 1,000 ft. per minute.

In large plants three or four sets of rolls are placed in series so as gradually to reduce the ore to the desired size. At Mount Morgan, such a plant consisted of eight sets of rolls in two series of four, thus :—

26 ins. diam.,	15 ins. face,	set	⅜ in. apart,	112 revs. per min.
26 ,,	15 ,,	,,	3/16 ,, ,,	,,
30 ,,	16 ,,	,,	1/16 ,, ,,	,,
30 ,,	16 ,,	,,	in contact	,,

The total power consumption was 100 h.p. and the crushing capacity 125 tons per 24 hours crushed to 20 mesh (0·025 in.); the wear on the steel roll-shells was 0·108 lb. of steel per ton of ore crushed.

Stamps.—The ordinary gravitation stamp is used more largely for gold milling than for other purposes, but also for crushing tinstone, etc. (though of late years in the treatment of gold ore is being largely superseded by ballmilling or tube milling and direct cyanidation). The complete stamp consists of the head, shoe, stem and tappet, the weight of which may be up to 1,500 lbs. The relative weights are about 30, 17, 40, 13. It is lifted by a cam forming the involute of a circle; if h be the lift of the stamp, r the radius of the pitch circle of the involute, and a the angular motion of the cam during the lift, $h = \frac{\pi r a}{180}$. The speed is usually about 90 drops per minute.

If n be the number of drops per minute, h the drop in inches, s the number of stamps, and w the weight of a stamp in pounds, the power required is approximately $\frac{nhsw}{300,000}$. (For a more exact formula see 'A Handbook of Gold Milling,' by H. Louis.) The average crushing capacity is 2–3 tons per 24 hours for a 1,000 lb. stamp. The Husband atmospheric stamp with two heads requires 35 h.p. to work it, and can crush 40 tons of hard tinstone per 24 hours down to 0·048 in. In modern practice on the Rand stamps are used as preliminary crushers, breaking to ½ to 1 in. and are much heavier than above given. (See *Bull. Inst. Min. Eng.*, No. 367, April 1935.)

Steam stamps are used mainly for crushing the copper-bearing rocks of the Lake Superior Mines, down to about ¼-in. mesh. One such stamp will crush 10 tons per hour, the efficiency being about 1·75 tons per i.h.p. per 24 hours.

Ball mills have been made both for dry and wet crushing. The Krupp mill is a dry-crushing mill; the No. 5 size, which is largely used, is 86 ins. diameter by 46 ins. length, makes 20–25 r.p.m., weighs 182 cwts., and a set of steel balls weighs 18 cwts. At Mount Morgan these mills require 13 h.p. and crush 22·7 tons per 24 hours to 20 mesh (0·025 in.). The balls wear at the rate of 0·725 lb. and the hunch plates at the rate of 0·681 lb. per ton of ore crushed.

Wet crushing ball mills are 60 ins. to 80 ins. in diameter and about 40 ins. long. A charge of balls for such a mill weighs about 2 tons; it is run at 25 to 30 r.p.m., takes from 25 to 35 h.p. to drive it, and will crush 25 to 100 tons down to 0·02 mesh per 24 hours; the water consumption is about 65 gallons per minute.

The tube mill is also used wet or dry, and is in effect an elongated ball mill, 3 ft. to 5 ft. in diameter and 13 ft. to 26 ft. long. A tube mill 4 ft. in diameter, 16 ft. 6 ins. long, crushed in Western Australia 38 tons of sand per 24 hours, 95 per cent. of the product being finer than 100 mesh, requiring 30 h.p. to drive it. Such mills are lined with silex, chilled iron, or hard steel bars, and are usually charged with flints. According to Mr. Davidson, the best number of r.p.m. $= 200 \div \sqrt{d}$, where d is the internal diameter in inches; the weight of flints in pounds should be $N \times 44$, where N is the internal capacity of the mill in cubic feet. Western Australian practice corresponds nearly to $N \times 60$.

The Marathon mill uses rods in place of balls; a mill 3 ft. diam., 7 ft. long, charged with 7,000 lbs. of rods ½ in. to 2 in. diam., running at 30 r.p.m., crushed 18 tons per hour with a consumption of 12·5 h.p., using 42 U.S.A. gallons of water per minute. The feed was below ¼-in. mesh and the product was ground to $\frac{1}{14}$-in. mesh, 14 per cent. being below $\frac{1}{200}$-in. mesh. The wear of the liner plates was 0·14 lb. and of the rods 0·4 lb. per ton of feed.

(*Trans. Amer. Inst. Min. Eng.*, lv., p. 678; lvii., p. 355.)

The Hardinge tube mill has the form of two cones base to base. An 8 ft. Hardinge mill requires 50 h.p. to drive it, and requires about 10 h.p. hours per ton crushed to about 48 mesh.

An 8 ft. × 22 ft. mill crushed 200–250 tons per 24 hrs. using about 56 h.p., with a charge of 5 tons of Danish pebbles wearing at the rate of 2·16 lbs. per ton of feed; with steel balls instead of pebbles 360–400 tons were crushed per 24 hours.

(*Trans. Amer. Inst. Min. Eng.*, lv., p. 678.)

The Marcy mill is a short mill (5–6 ft.) with perforated diaphragm at the discharge end, from 2 ins. to 48 mesh. An 8 ft. by 6 ft. mill driven by a 225 h.p. motor crushes 550 tons per 24 hours at 24 r.p.m., carrying 30,000 lbs. chrome steel balls.

(*C. T. Van Winkle, Trans. Amer. Inst. Min. Eng.*, vol. lix. (1918), p. 227.)

The Huntingdon mill is made in three sizes, 3 ft. 6 ins., 5 ft. and 6 ft. diam.; No. 2 is most used; it weighs about 5 tons; consumes 12 h.p.; makes 60–70 r.p.m., and will crush about 10 tons per 24 hours to about 15 mesh.

The Arrastra is 10 to 20 ft. in diameter, has usually four dragstones, 6–8 cwts. in weight. At 6 to 12 r.p.m. a charge of 1 to 3 tons is ground in 2–3 hours.

The Chilian mill has 2–3 rollers, 4 to 6 ft. in diameter, takes up to 75 h.p., and crushes up to 150 tons per 24 hours.

Sizing.—For coarse screening fixed grizzlies or 'jigging' screens are used. For medium and fine screening mostly trommels, 3 ft. to 2 ft. in diameter by 12 ft. to 3 ft. long; the peripheral velocity is usually 50 to 200 ft. per minute. The slopes may vary from 5° to 14°,

averaging about 7°. A set of seven trommels, 3 ft. diam., 5 ft. long, will size about 7 tons of ordinary crushed material per hour, and require up to 5 h.p. to drive it. For the finest work vibrating screens are used. Wedge wire is often used for the screening surface.

Classification.—This term applies to the separation into groups of equal falling particles.

It is to Stokes and Rittinger (1867) and to Pernolet that we owe our knowledge as to the limits within which it is practicable to separate minerals into classes according to size by means of screens before washing. They arrived at the conclusion that water was the best medium for the separation of the separate grains.

If we accept Rittinger's theory that it is necessary to size before washing, the theory being that a grain falling in still water attains a certain maximum velocity of fall *determined by its diameter and specific gravity* at an early period of its first second of fall.

Taking D = diameter of the grain.
δ = specific gravity of the substance.
V = maximum velocity of fall.

$$\text{then } V = \sqrt{D}\,(\delta - 1)$$

and assuming c is a coefficient whose value depends upon the resistance offered by the water,

$$\text{then } V = C\sqrt{D}\,(\delta - 1)$$

Deduced thus:—

Consider a particle of mineral of specific gravity δ and diameter D falling in water.

Then the weight in water = weight in air − weight of water displaced.

$$\text{Therefore the weight in water} = cD^3\delta - cD^3$$

(where c is a constant depending entirely on the shape of the particle, *e.g.* the contents of a sphere = diameter^3 × ·5236. Therefore c = ·5236 if the particle be an exact sphere).

Assuming the specific gravity of the body were 2 then the volume × 2 × 62·5 = the weight of the body, but 62·5 is common and therefore may be eliminated.

$$\text{Hence } cD^3\delta - cD^3 = cD^3(d - 1) \quad . \quad . \quad . \quad . \quad (1)$$

For small velocities the resistance to the motion of the particle in a fluid is proportionate to the square of the velocity.

Therefore, if the velocity of fall at any time be V

$$R \propto k_1V^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

R being the resistance and k_1 a coefficient. It is known also that R is proportionate to the are of the falling particle, hence to D^2 (diameter squared) therefore

$$R \propto k_2D^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

k_2 being a coefficient

Combining (not multiplying) (2) and (3)

$$R = kD^2V^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

k being compounded of k_1 and k_2.

The particle will fall with increasing velocity until the resistance to motion becomes equal to the downward force, when it will proceed with a uniform velocity. To find the uniform velocity equate (1) and (4) (*i.e.* equate the resistance R and the weight in water)

$$\text{Then } cD^3(\delta - 1) = kD^2V^2$$
$$V^2 = \eta D(\delta - 1)$$
$$V = \sqrt{\eta D(\delta - 1)} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where η is compounded of k and c

If we take two bodies of the same shape, but of different diameters D_1 D_2 and of different specific gravity, for these two bodies to fall together in water

$$\sqrt{\eta D_1(\delta_1 - 1)} \text{ must equal } \sqrt{\eta D_2(\delta_2 - 1)}$$

which is known as Pernolet's formulae. Dividing each side of the equation by

$$\sqrt{\eta D_2(\delta_1 - 1)} \text{ we have}$$
$$\frac{D_1}{D_2} = \frac{\delta_2 - 1}{\delta_1 - 1} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

If we take for instance two bodies of such widely different specific gravities as say quartz (sp. gr. 2·5 approximately) and galena (sp. gr. 7·5 approximately), in order to find the relative diameters of the two particles (D_1 and D_2) which will permit of these two substances falling together in water.

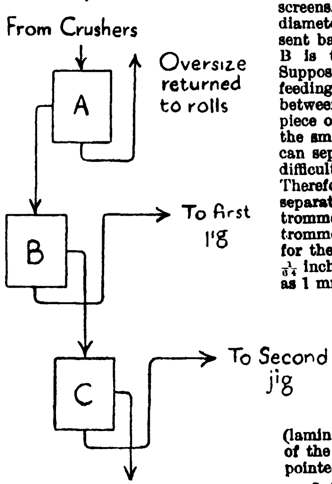
From the equation (6)

$$\frac{D_1}{D_2} = \frac{7\cdot5 - 1}{2\cdot5 - 1} = \frac{6\cdot5}{1\cdot5} = 4 \text{ nearly.}$$

So that if we have a particle of quartz four times the diameter of galena, the two particles will fall together in water. If the quartz be more than four times the diameter of the galena it will fall quicker, and if less than four times the size of the galena, slower than the galena. Hence in jigging the two substances in a washer, if we want the galena to fall first, *i.e.* reach the bottom first,

no particles of the quartz must be greater than four times the size of the smallest particles of galena.

As a practical example of the application of Pernolet's formula, let us take the case of a mixture of quartz and galena. To determine the *sieve scale* for an ore containing these two substances: Take A, B and C in accompanying figure to represent three trommels or cylindrical sieves or screens, and suppose that trommel A has holes 1 in. in diameter, any material less than 1 in. in diameter being sent back to the rolls to be recrushed. The stuff entering B is therefore something less than 1 in. in diameter. Suppose the holes in B to be x inch in diameter, the stuff feeding into the first jig or washer is therefore anything between 1 inch and x inch in diameter: *i.e.* the largest piece of quartz passing to this jig is 1 in. in diameter and the smallest piece of galena is x in. in diameter. If the jig can separate these two pieces (which constitute the most difficult case) then it will separate all the intermediate sizes. Therefore if x be made ¼ inch we shall have complete separation. By the same reasoning the size of the holes in trommel C would be made one quarter the size of those in trommel B, namely $\frac{1}{4} \times \frac{1}{4} = \frac{1}{16}$ inch. Hence the sieve scale for the ore in question would be 1 inch, ¼ inch, $\frac{1}{16}$ inch, $\frac{1}{64}$ inch (though in practice one could not go beyond ¼ inch.: as 1 mm. may be taken as the limit of successful screening).



But in regard to all these calculations it must be borne in mind that Rittinger and Stokes's law of falling bodies in water holds good only for true spheres, and requires variable constants in order that the formulæ may be made applicable to particles of other shape, and where there is presented a mixture containing such different shapes as coal (more or less cubical) and shale (laminations), or porous particles such as fusain the value of the formulæ based on Stokes's law, as Dr. Lessing has pointed out, is very much diminished.*

Spitzkasten: the first box should be 2 ft. wide for 10 cub. ft. pulp per minute, or 1–2 cwts. of solid matter; boxes may increase in geometrical progression with factor of 1·5; length of first box about 6 ft., increasing by 3 ft. for each successive box.

Trough classifiers 10 to 20 ft. long, 1 ft. wide at narrow end, will treat 100 tons per 24 hours with 100 cub. ft. of water per ton of crushed material.

Jigs.—The following represents the general modern practice:—

Diam. of particle	0·25	0·50	0·75	1·00	1·25	1·50	1·75	2·00 ins.
Length of stroke	0·4	1·2	1·55	1·8	2·0	0·15	2·3	2·4
No. of strokes per min.	200	160	145	130	125	125	125	125

CONTINENTAL JIGGING PRACTICE ON ORDINARY LEAD-ZINC ORES.

Three to five compartment jigs; screen surface 20″ × 31·5″.

Size of Particles.	Length of Stroke.	Strokes per Min.	Water per Cwt. treated.	Capacity per Sq. Ft. of Screen Area per Hour.
Inch.	Inch.		Gallons.	Cwt.
0·04	0·2	280	90	0·6
0·046 to 0·06	0·25	280	73	0·9
0·06 to 0·08	0·35	260	60	1·2
0·08 to 0·11	0·50	240	55	1·6
0·11 to 0·16	0·60	220	52	1·8
0·16 to 0·22	0·80	200	50	1·9
0·22 to 0·32	1·00	180	46	2·0
0·32 to 0·43	1·20	160	45	2·1
0·43 to 0·63	1·25	140	54	2·2
0·63 to 0·87	1·60	140	58	3·7
0·87 to 1·25	2·00	140	61	4·3

* See chapter X of Vol. 5 of 'Modern Practice in Mining,' by R. A. S. Redmayne, from which the above is extracted.

Jig screens of steel wire are liable to rapid corrosion when pyritic ores are being treated ; wire drawn from Ambrac (Cu75Ni20Zn5) has been recommended in such cases. Mechanical control has been introduced by several makers.

Round buddle; diam. 18 ft. to 25 ft.; brush makes 5–10 r.p.m. Capacity 1½–2 cub. ft. per min. carrying 28 to 56 lbs. material; time of filling 3–10 hours.

Slime table; diam. 15 ft. to 25 ft.; ¼–1 r.p.m. Pulp 1½–3 cub. ft. per min., carrying 4 to 7 lbs. per cub. ft. Clear water 1½–3 cub. ft. per min. Power required ½–1½ h.

Frue vanner; belt surface 4 ft. by 12 ft.; fall 3 ins. to 6 ins.; travel 6 ft. per min.; strokes 200 per min. Capacity 0·25 to 0·5 cub. ft. pulp per min.; 5 to 8 tons material per 24 hours. Clear water ½ of pulp. Power required ½ h.p.

Lühring vanner; belt surface 3 ft. 6 ins. by 12 ft.; travel 8–12 ft. per min.; 160–180 strokes per min. Capacity 2½–7½ tons per 24 hours; clear water 1–2 cub. ft. per min. Power required ⅓–½ h.p.

Wilfley table; 16 ft. long, 6 ft. wide, tapering to 3 ft. Will take particles up to ¼ in. 240 strokes per min., ¾ in. long. Capacity 25 to 50 tons per 24 hours. Clear water 1 to 3 cub. ft. per min. Power required 1 h.p.

Coal Cleaning.*

Coal as it comes from the mine is first screened, usually over a 2 ins. to 2¾ ins. screen ; the oversize drops on to picking belts, where shale, dirty coal, etc., are picked out. The undersize is taken to a cleaning plant (wet or dry), especially when it is required for coke-making. A jigging screen with ⅜-in. holes will screen about 1 ton per hour for each 0·75 sq. ft. of screening surface.

Coal is sometimes dry-cleaned in the Purdee spiral separator, in which it is allowed to slide down a spiral track, the clean coal falling over the outer edge, whilst the shale, etc., remains on the track.

When the separation of the clean coal from the accompanying shaly matter is easy, or when the products are not required in the highest possible state of purity, a simple form of washer may be used. Such is, e.g., the Elliott trough washer, capable of treating 5 to 10 tons of small coal per hour with a water consumption of 1,750 gallons per ton of coal washed. The Blackett washer is similar in principle, but the fixed trough with the moving dam-plates is replaced by a revolving drum within which is a spiral baffle-plate; it will treat 10 tons of small coal per hour, requiring 3,000 gallons of water in circulation per ton of coal washed. The Robinson washer works on the principle of a spitzkasten, with upward flow of water and a revolving stirrer ; it can treat 15 to 20 tons of small coal per hou .

The purity of the washed coal is usually determined by floating it in solutions of known specific gravity ; coal that floats in solutions of sp. gr. 1·35 to 1·45 is generally considered clean coal. The washing characteristics of a coal are best determined by constructing a washability curve or Henry curve. (See 'Modern Practice in Mining,' vol. v, pp. 432–437, by R. A. S. Redmayne, 1932.) The washability of coals is generally determined by plotting the proportions of the whole which float in solutions of definite specific gravities against the ash contents of these fractions as a curve, from the shape of which much valuable information as to the washing properties of the coal may be obtained.

Most plants for complete washing make use of jigs (bashes or boxes), and the coarser refuse is sometimes crushed and re-washed. See flow-sheet No. 1., p. 919.

The following details are given as explanatory of one form of washer. The unwashed coal, say under 2 ins. to 3 ins., is sized before washing. The washing is carried out in two types of boxes, viz.: (*a*) Small coal felspar boxes, which treat all the coal below ½ in.; (*b*) nut coal type of box, which treats the various sizes below 3 ins. and above ½ in. These sizes vary according to local conditions and the requirements of the market. The nut washers are 8 ft. deep, and the sieves are 5 ft. long and 3 ft. to 5 ft. wide, each washer treating 2·5 to 3·5 tons per hour per foot of width of screen. The more important data affecting the operations of nut washers are shown in the following table :—

* See 'The Preparation of Coal for the Market,' by H. Louis, 1928; and 'Preparation of Coal for the Market' in 'Modern Practice in Mining,' vol. v, by R. A. S. Redmayne, 1932.

Size of Nuts.	Depth of Layer of Shale on Sieve.	Length of Stroke.	No. of Stroke per Minute.	Mesh of Sieve.
½ in. to ¾ in.	2½ ins.	2½ ins.	80	$\frac{1}{10}$ in.
¾ " " 1 "	3 "	3 "	75	⅛ "
1 " " 2 ins.	3½ "	3½ "	70	¼ "
2 ins. " 3½ "	4½ "	4¾ "	65	$\frac{3}{10}$ "
3½ " " 5 "	5½ "	6¾ "	60	$\frac{3}{20}$ "

The Felspar Washer is built in two compartments, each 4 ft. long, making a total length of 8 ft. by 2 ft. 6 ins. wide, the box being 5 ft. deep; such a washer can wash 7 to 10 tons of small coal per hour up to ½ in. in size. The following are the leading data:—

	1st Compartment.	2nd Compartment.
Thickness of layer of felspar	2½ ins.	2½ ins.
" " shale	$\frac{4}{10}$ in.	$\frac{2}{10}$ in.
Size of pieces of felspar	$\frac{8}{10}$ in. to 1 in.	$\frac{5}{10}$ in. to $\frac{8}{10}$ in.
Length of stroke	0·55 in.	0·47 in.
No. of strokes per minute	165	165
Mesh of screen	0·55 in.	0·47 in.

A plant to wash 100 tons per hour, 50 per cent. on nut washers and 50 per cent. on felspar washers, would require four of the former, 4 ft. wide, and six of the latter. Such a plant would require in circulation about 135,000 gallons of water, and make-up water amounting to between 2,800 and 3,500 gallons per hour.

When the refuse from the nut washers contains sufficient intergrown coal to be worth treating, it is crushed, generally in a disintegrator, and the crushed material is re-washed on felspar washers.

A coal washery may require from 1·5 to 3·5 h.p. for each ton of unwashed coal treated per hour, varying with (*a*) the total output of the washery (a large washery requiring a relatively smaller h.p. per ton); (*b*) the quantity of interstratified coal, and whether the larger size is crushed and washed together with the smaller size, or whether the smaller size only is re-washed; (*c*) the type and capacity of draining and storage bunkers, and whether apparatus is installed for mixing the various products.

Messrs. Simon-Carves, Limited, build washeries on the so-called Baum principle, in which washing precedes classification. The slack below about 2 ins. is delivered to a bash having an area of about 0·8 sq. ft. per ton per hour; the washed coal then passes to a screen of about ⅜-in. mesh; the over-size is clean coal, and the under-size goes to a second bash having an area of about 1 sq. ft. per ton of coal per hour, the product being clean coal and refuse. The dirt produced in the first washing can be further crushed and washed over again if necessary. A plant to treat 100 tons of slack per hour would, therefore, require a first bash with an area of 80 sq. ft., and a second bash with an area of 100 sq. ft.; the water in circulation would be about 130,000 gallons per hour, and the make-up water required about 2,500 gallons.

The rhéolaveur consists of a series of troughs of steel, cement or wood, sometimes lined with tiles, fitted with a series of pockets with adjustable discharges and, for the coarser sizes of coal, with upward water flows. These are arranged so as to discharge clean coal, refuse or middlings for re-washing as may be required. The plant is relatively cheap, compact and efficient and can treat all sizes from 4 in. to slurry. No general figures can be given as the plant has to be specially designed for each case. It is largely used in Belgium, and altogether about 60 million tons of coal a year are treated by it.

At Grassmoor Colliery a rhéolaveur plant treats 100 tons per hour 0-1 in. in two sizes, 40 tons 0-⅜ in., 60 tons ⅜-1 in., absorbs 105 h.p., uses 140,000 gals. water in circulation.

(*A. Audry*, *Proc. So. Wales Inst. Eng.*, vol. xli., p. 567.)

(See 'The Rhéolaveur Coal-Washer in Belgium,' by H. Briggs and H. Louis, *Trans. Inst. Min. Eng.*, vol. lxxiv., 1928, p. 285; also 'The Operation of a Small-coal Washer,' by C. E. Pulford, *Trans. Inst. Min. Eng.*, vol. lxxviii., 1929, p. 47.)

The Hoyois process, used in the North of France, is not dissimilar.

In the United States small coal is being largely washed on shaking tables of the Wilfley type; such a table will treat 5 to 8 tons per hour under ⅜-in. mesh, requiring about 1 h.p.

The flotation process has been applied to washing fine coal to a very small extent in Britain but extensively in Spanish collieries.

The Chance process employs a separating cone worked with a sludge consisting of sand and water; it is said to give excellent results on Anthracite, and is used in the U.S.A. (See *Trans. Amer. Inst. Min. Met. Eng.*, vol. lxx., p. 740.)

The Lessing process uses a solution of calcium chloride as a separating medium. This process was used by Sir Henry Bessemer in 1858.

One of the principal difficulties in coal washing is presented by the fine coal (say $\frac{1}{30}$ in.), which forms slurry when suspended in water; it consists often largely of fusain, and is therefore non-coking and is often very impure. It may be collected in settling tanks, which, however, occupy much ground space. Most makers of washing plant supply an elevated conical settling tank, from which a thickened slurry can be drawn off from the bottom, whilst tolerably clean water is drawn off from the top. A still better device is the Dorr Thickener, usually between 50 and 100 ft. in diameter, though made up to 200 ft. diameter and about 10 ft. deep; the stirrer makes 4–8 revs. per hr., and 100 sq. ft. of thickener area are allowed for each 25 gals. per min. The Rheolaveur deals efficiently with all but the finest slurry. A recent device is the Kirkless Slurry Separator, which filters the slurry. It is generally considered preferable to blow out the dust or draw it off by an aspirator before the coal goes to the cleaning plant if the coal is dry enough. The dust is collected in cyclones, bag filters, etc., and is generally very suitable for dust firing, though it may need further grinding for this purpose. Some form of starch is sometimes used to 'settle' slurry.

Dry Cleaning.—The American Coal Cleaning Corporation's machine consists of a shaking table with riffles and a porous deck through which a current of air ascends on the principle of the Sutton-Steele table; this cleans dry coal and the finished product contains under 2 per cent. of extrinsic ash. Over 10,000,000 tons of coal were cleaned in this way in 1927 in the U.S.A. (See *Trans. Amer. Inst. Min. Met. Eng.*, vol. lxx., p. 758.)

The largest American plant is the McComas plant at Crane Creek Mines, W. Virginia, treating 225 tons per hour. The Berwind White Colliery Co. has at present the biggest dry cleaning plant in existence.

This table has been introduced into England by the Birtley Iron Company, Ltd. Its first form, known as the Birtley SJ Table, has been erected in a number of places, one of the first being at Wardley Colliery, Co. Durham. This plant treats coal under 2½ in. and consists of six SJ tables with dust aspirator and baghouse. It cleans to within 2 per cent of the intrinsic ash (by which is understood the ash occurring as part of the coal) leaving about 1 per cent. of free coal in the refuse. Its original capacity was 125 tons per hour, but this has subsequently been increased.

An improved form, known as the Y Table, was introduced about 1926, having double the capacity of the SJ Table, and not needing as close sizing. A still newer form known as the V separator, made in two types, the standard V and the super V, has been introduced; the former has about three-fourths of the capacity of the latter, which is as follows on average coal:

2 in. to ½ in.	60 tons per hour
½ „ „ ⅛ in.	40 „ „
Below ⅛ in.	20 „ „

The power consumption for the fan and drive of these machines averages about 0·75 h.p. per hour. The Birtley Company has constructed numerous plants in England, eight were under construction in 1930, and the total operating cost, including labour, maintenance and repairs, is given at about 2·25*d.* per ton. (See papers by K. C. Appleyard, *Trans. Inst. M.E.*, vol. lxxiii., 1927, p. 404, and World Power Fuel Conference, 1928, No. C 7.)

In 1935 there were 82 plants erected, including about 12 that represented increases in existing plant and 5 under erection.

Another table used recently in this country is the Static dry cleaner of G. Raw. It consists of a long relatively narrow table, without riffles, but with three skimmers; the bed of the table is, like the last, of perforated material, but a pulsating current instead of a continuous current is introduced into the air-chest beneath the bed. The tables have capacities of from 30 to 50 tons per hr. and the power consumption is 0·85 B.O.T. unit for a ton of coal. Costs including labour, power, maintenance, interest and depreciation, are given at 3½d. per ton (see paper by G. Raw and F. F. Ridley, World Power Fuel Conference, 1928, No. C 6). Another dry coal-cleaning table is the Kirkup table, in which the table is at rest, but receives a pulsating air current beneath its perforated bed. The Peale-Davis table is like a Birtley Y table, 40 ft. long, 14 ft. wide, with a capacity up to 250 tons per hr. This is being used at Nunnery in Yorkshire and at Bedwas in South Wales.

The dry cleaning of coal has these advantages over the wet processes:

(*a*) There is no water to be obtained, handled and clarified.

(*b*) The coal has not to be drained of water.

(*c*) There is no absorption of water by the coal.

(*d*) There being no wet coal, the difficulty of dealing with frozen coal in wagons in winter does not arise.

(*e*) The dryer the coal, other things being equal, the higher its calorific value. Coals to which the dry process is particularly applicable are :—

(*a*) A coal subject to discoloration owing to the presence of lime, if treated by water.

(*b*) Coal friable in character which under wet cleaning would absorb much water, hygroscopically and externally.

(*c*) Which are to be subjected to carbonisation, when the presence of water is an obvious disadvantage.

In some cases dry cleaning may with advantage be combined with washing, the coal below, say, $\frac{5}{8}$ in. going to a dry-cleaning plant and the coarser coal to a washery ; the washed coal after drainage is mixed with the dry-cleaned coal and the product carries a proportion of moisture suitable for many purposes.

(See also 'The Dry Cleaning of Coal,' by H. Louis, *Fuel Economy Review*, 1928.)

Dust is now occasionally removed from coal that is not naturally too wet before it is cleaned by washing or dry-cleaning ; it may be screened off by fine vibrating screens or may be taken out by an air current either on the screens or on the dry cleaning tables or else in a dust extractor ; the dust is collected by cyclones and bag-houses and is often used for dust-firing. Wedge wire is occasionally used for the fine screens. The Waring dust collector is being used successfully. (See *Min. Mag.*, Dec. 1928.)

Vibrating screens have a tightly stretched screening surface kept in rapid vibration and set at a tolerably steep angle ; the Hummer, Hayle, Overstrom, etc., screens differ mainly in the mechanism by which the vibration is produced.

For a good comparison of different methods of coal-cleaning see paper by Wheeler and Chapman in report of the Coal-Cleaning Conference at Edinburgh, July, 1927, pub. by Soc. Chem. Ind.

Mr. Norman Kemp has applied X-ray analysis to the products of the coal washery.

(*Trans. Inst. Min. Eng.*, vol. lxvii., p. 59.)

Magnetic Separation.

Maxima of magnetic susceptibility of minerals by volume in C.G.S.

Common non-ferrous minerals, *e.g.* mica, quartz, felspar, calcite, have susceptibilities $<$ 0·000001. 'Strongly' magnetic minerals have susceptibilities $>$ 0·001. 'Feebly' magnetic minerals between 0·001 and 0·0001.

(*After Prof. Ernest Wilson.*)

MAGNETIC SEPARATORS.

As examples of the capacity of modern magnetic separators we give the following figures :—

Dry Work.—Drum, 24 ins. diameter with 24 ins. face ; capacity 12 tons per hour ; will take lumps up to 20 lbs. in weight.

An electro-magnetic separator with six magnetic fields with maximum current on the four magnetic poles takes 12 amp. at 100 volts.

Flotation Processes.

These may be classified as follows :—

I. *Film Flotation*, utilising differences of surface tension on particles at an air-water interface—*e.g.* De Bavay, Macquisten processes.

II. *Oil Flotation*, utilising differences of surface tension in an oil-water medium where the particles are buoyed up by oil—*e.g.* First Elmore process.

III. *Adhesive Processes*, utilising differences of surface tension between particles and oil or grease, causing differential adhesion to oiled or greased surfaces—*e.g.* Murex, Cattermole, greased-plate processes.

IV. *Froth Flotation*, utilising differences of surface tension at gas-water interfaces, where the particles are buoyed up by bubbles of gas :—

(*a*) Where the bubbles are produced by chemical action—*e.g.* Potter, Delprat processes.

(*b*) Where the bubbles are produced by releasing the air dissolved in water—*e.g.* Elmore vacuum process.

(*c*) Where the bubbles are produced by mechanical means—*e.g.* Minerals Separation, Callow, Janey, K. & K. (Kraut & Kolberg), Rork, Kleinbentink, Ekof, Fagergren processes.

(See 'Froth Flotation : its Commercial Application and its Influence on Modern Concentration and Smelting Practice,' Walter Broadbridge, *Trans. Inst. M. M.*, vol. xxix., p. 205, 1920. (*Ralston.*)

Reagents used :—

Gangue modifying :—Acids, alkalies, silicates carbonates, and other salts.

Froth producing :—Soluble oils, essential oils, cresylic acid, amyl alcohol, etc.

Froth stabilising :—Insoluble oils, petroleum, etc.

According to figures collected by the United States Bureau of Mines, a total of 50,073,450 tons of ore was treated in the United States by the flotation process in 1927. By far the greater portion, 40,881,768 tons, consisted of copper ores. The remainder was made up of complex lead-zinc, lead, zinc, copper-iron, and miscellaneous ores. A total of 220,514,373 lbs. of reagents was consumed in the treatment by flotation of all classes of ores. The bulk of this consumption was lime, of which 169,926,145 lbs. were consumed. Pine oils constituted the greater portion of the frothing reagents used, accounting for 5,064,320 of a total of 6,583,151 lbs. Appreciable amounts of cresols were also used. Of the oils used as collecting reagents, coal-tar creosotes and coal tar made up 2,655,352 of a total of 3,508,993 lbs. Other oils used as collecting reagents were wood-tar creosote, crude oils, petroleum products, blast-furnace oils, water-gas oils and tars, and miscellaneous and reconstructed oils. Ethyl xanthates and di-thio-phosphoric acids were used as collecting reagents to the extent of 3,319,639 lbs. and 1,932,996 lbs. respectively, and made up the great bulk of chemicals used for this purpose. Other chemicals used were higher xanthates (amyl and butyl), thio-carbanilide, alpha-naphthylamine, thio-ureas, and oleic acid. The acids and alkalis used in addition to the great consumption of lime were composed of sulphuric acid, hydrochloric acid, sodium carbonate, sodium bicarbonate, sodium hydroxide, barium

carbonate, and cement. Other inorganic reagents used included sodium sulphide, calcium and barium sulphides, copper sulphate, cyanides, sodium sulphite, sodium silicate, zinc sulphate, sodium dichromate, tri-sodium phosphate, aluminium sulphate, sulphur, calcium chloride, and sodium chloride. Some quantities of glue and starch were used as protective organic colloids.
(*The Chemical Age*, July 6, 1929.)

Surface Tension of Liquids against Air.

	Dynes per sq. cm.			Dynes per sq. cm.
Water (at 0° C.)	75·8	Water with 0·14 per cent. cresol	(at 23° C.)	71·5
Water („ 20° C.)	75·1	Water with 0·14 per cent. amyl alcohol	(„ 23° C.)	68·4
Phenol („ 41° C.)	37·0	Water with 0·134 per cent. saponine	(„ 23° C.)	48·7
Cresol	34·8	Water with eucalyptus 'solute'	(„ 20° C.)	44·6
Olive oil	32·0			
Petroleum	27·7			
Turpentine	25·6			

Dilute sulphuric acid reduces the contact angle and hysteresis range of that angle far more for quartz, silicates, and oxides than it does for metallic sulphides; oiling the latter greatly increases the contact angle and the hysteresis range.
(*H. L. Sulman*, 'A Contribution to the Study of Flotation,' *Trans. Inst. Min. Met.*, vol. xxix., 1920.)

The Inspiration Consolidated Copper Company's plant at Miami, Arizona, treats 15,000 tons in 24 hours. The ore contains 1¾ per cent. of copper, mainly in finely disseminated sulphides. Flotation reagents used, 1¼ lbs. per ton of ore. Recovery, 85 per cent. of total copper, 90 per cent. of copper present as sulphide; concentrates contain 20 per cent. of copper.
(*Trans. Amer. Inst. Min. Eng.*, lv., 1916, p. 576.)

Selective flotation is very largely employed for the treatment of lead-zinc ores in the Western States and in Mexico. (See 'Selective Flotation as Applied to Canadian Ores.' C. S. Parsons, *Canad. Min. Journ.*, 1927, vol. xlviii., p. 468; also 'The Trend of Flotation,' Weinig & Palmer, *Colorado Sch. of Mines Quart.*, 1926, vol. xxi., No. 2.)

Finely ground coal may be froth-floated from shale, using 1 lb. of cresol and ¼ lb. of paraffin, per ton of coaly shale; the shale contains about 65 per cent. of ash, the clean coal about 8 per cent. Potassic Xanthate is also used.

ELECTROSTATIC SEPARATION is used in some special cases—*e.g.* for concentrating rosin blende, molybdenite, and graphite (Blake-Marsden and Huff processes).

DRY SEPARATORS, using currents of air instead of water, are used for ores under exceptional conditions.

The Advisory Technical Committee in its Report to the Minister of Fuel and Power (1945) states that at present far too much hand picking of coal goes on, which is extravagant in man-power and has only been justified by the higher prices which have been obtained in the past for the large coal sorted in this way. The Committee points to the fact that in some Continental mines, despite the use of pneumatic picks for getting the coal, the whole of the product, with the exception of the largest lumps, which are hand-picked, is washed.

The Committee is of the opinion that with power loading of coal at the face (under which system a greater admixture of dirt may be expected), washing (with breaking of lumps of about 10 ins. and upwards) of the entire output should become general. At present (1939), only about 47 per cent. of the British coal output is subjected to washing.

All new coal treatment plants should, the Committee states, be appropriately equipped to treat fine coals and render them saleable. Dry fines can be separated by 'aspiration' and all fines can be cleaned by 'froth flotation.'

FLOW SHEETS.

The diagrams given on pp. 919–927 are specimen flow sheets, illustrating the sequence of operations in certain typical cases:—

GOLD MILLING.

With the improvements in the cyanide practice and also with the exhaustion of the rich free milling surface ores of various camps, which rendered such improvements necessary, have come changes in the process of treating gold ores. Instead of the simple Californian practice of crushing by 900 lb. stamps to about 40 mesh, amalgamating either in or outside the battery, concentrating the sulphides on vanners or shaking tables, chlorinating the concentrates, and sometimes treating the tailings by cyanidation, the 'all-sliming' process has come into force.

As practised on the Rand, the ore is screened through grizzlies with bars 2¾ ins. apart, the oversize going to a sorting belt, thence to a crusher. The ore passes into a feeder, thence to stamps weighing 2,000 lbs. per head, where it is crushed to pass a 10-mesh discharge screen. The pulp is classified in cones and the coarse product delivered to tube mills where it is slimed. The product of the tube mills, together with the overflow from the classifying cones, is delivered to the amalgamating tables. From the tables it is again classified, the sands being cyanided direct, and the slimes treated by air agitation, then filter-pressed or vacuum-filtered.

The most vital changes from the old practice to the new have been: the use of the heavy gravity stamp merely as a preliminary coarse crusher for the tube mills; the adoption of the tube mills for fine grinding and the employment of the tall, air-agitation tanks and of filters.

The practice is modified in each district, the modification depending largely upon the nature of the ore. In some camps silver ores are being successfully treated by fine crushing and cyaniding.

Cyanide Process.

This process may be conducted in a number of different methods, which may be classified as follows:—

I. Coarse crushing and direct cyanidation (exceptional).

II. Fine crushing with:—

- A. Simultaneous cyanidation.
- B. Subsequent cyanidation without classification.
- C. Subsequent cyanidation, preceded by classification into (*a*) sand, (*b*) slime.
  - (*a*) Sand cyanidation, generally by percolation.
  - (*b*) Slime cyanidation, performed by
    1. Decantation.
    2. Agitation (mechanical or pneumatic) and filtration.
    3. Direct cyanidation in filters.
- D. All sliming methods with simultaneous or subsequent filtration.

(*H. Louis*, '*Handbook of Metallurgy*,' I, p. 1031, 3rd edn., Schnabel and Louis.)

Filtration methods may be classified as under:—

I. Suction filters, divided into:—
- (*a*) Filters forming a thin cake, continuous acting.
- (*b*) Filters forming a thick cake, intermittent.

II. Pressure filters, divided into:—
- (*c*) Ordinary filter presses.
- (*d*) Sluicing filter presses.
- (*e*) Filtering chambers or cylinders.

III. Centrifugal filters.

(*S. J. Young*, '*Trans. Amer. Inst. M.E.*,' xlii., 1911, p. 752.)

Precipitation is performed by zinc shavings, zinc-lead shavings, zinc dust, aluminium electrolysis.

An average cyanide plant may be roughly estimated to cost complete $1,000 per ton treated per day in the Western States. An average cost of cyaniding, including crushing, is now about $1.50 per ton, but varies within very wide limits.

Stamps.

The duty of stamps depends upon the nature of the ore, the weight of the stamp, its speed and drop, the size of the aperture of discharge screen, and the height of the discharge. The following table gives the duty per stamp in various districts :—

DUTY OF STAMPS.

Mine or District.	Weight of Stamp.	Drop in Inches	Number of drops per Min.	Screen Aperture.	Discharge in Inches.	Tons Crushed per head per 24 Hrs.	Remarks.
California . .	900 lbs.	7	90	900 per sq. in.	4	3	Gold Quartz
Melones, Cal. .	1,000 "	7	104	20 mesh	—	4·41	
Tonopah Mill, U.S.A.	1,050 "	6½	104	slot ·04 in. wide	2½	5·09	Gold and Silver
Montana-Tonopah, U.S.A.	1,050 "	7	100	20 mesh	3	3·3	Gold and Silver
Tonopah Belmont, U.S.A.	1,050 "	6	104	24 mesh	—	3·7	"
Goldfield, U.S.A..	1,050 "	7	108	12 mesh	—	6	"
Komata Reefs Mine	1,030 "	6½	100	4½ holes per in.	4	5	Gold
Luipaards Vlei Rand	1,629 "	8½	98·6	200 holes per sq. in.	4	9·6	"
Simmer & Jack East	1,550 "	8	96	200 holes per sq. in.	3½	8·3	"
Waihi Grand Junction	1,110 "	7	105	5 to 10 mesh	1½	7·6	"
Oroya Brownhill.	1,100 "	7¾	108	10 mesh	2	6·48	"
Ivanhoe . .	1,192 "	7½	104	225 mesh	2	5½	"
Gt. Fingall . .	1,150 "	8	106	12 mesh	3	7	"
Mysore Gold Mine, Mysore, India	1,150 "	7·5	96	1,200, 625 and 400 per sq. in.	3	3·63	"

It is claimed that the new 2,000 lb. stamps of the Goldfields (S.A.) are capable of crushing 26 tons of ore per stamp per 24 hours by introducing an elimination screen to ' bypass ' the fine material from the rock bins direct to the tube mill and using screens with aperture of ·284 inch.

Amount of water varies on the Rand, from 5 to 10 tons of battery water to one of ore, depending upon the duty. In Western Australia the amount of water required is 4 to 8 gallons of water per stamp per minute.

Power per stamp.—The 2,000 lb. stamp requires 5 h.p. per stamp. In Nevada, for 1,250 lb. stamp 3·5 h.p. per stamp is used. At the Goldfield Con. in Nevada with 140 stamps, fine grinding and cyaniding, 1,600 h.p. is supplied to the mill or 1·73 h.p. per ton of ore milled.

COST OF EQUIPMENT OF GOLD MILLS.

The following is the comparative cost of gold mills, including all machinery and buildings :—

Mill.	Number of Stamps.	Cost of Machinery and Plant.	Cost per Stamp.
Rand Mill	200	£334,000	£1,670
New Kleinfontein	200	420,480	2,102
Wit Deep	200	346,210	1,731
Robinson Central Deep . . .	100 and Tube Mill	234,013	2,340
Great Fingall	"	193,745	1,937
El Oro	"	160,000	1,600

In Nevada, the cost of complete plants doing fine grinding and slimes filtering is 1,400*l.* a stamp.

Tube Mills

are used as secondary crushers following the stamps. On the Rand they are most efficient when fed with ore that has been crushed through a screen the apertures of which are ·27 in. or say ¼ in. They are here 25 ft. in length by 5½ ft. in diameter, and one tube mill crushes the product of 10 stamps. Each tube mill requires 100 h.p. to drive it. In New Zealand tube mills are 16 ft. by 4 ft. revolving at 29 r.p.m., and driven by 25 h.p. motor. The feed is 1½ parts of water by weight to 1 part of ore. In 22 months a tube mill ground 28,500 tons of hard quartz, 50 per cent. of which passed through a 200-mesh screen.

At Pachuca 90 h.p. is used for a 5 ft. 6 ins. by 22 ft. tube mill. Output 140 tons per day through a 60-mesh screen.

At Waihi Grand Junction tube mills 19 ft. 3 ins. long by 4 ft. 8 ins. diameter require 42 h.p. Those 16 ft. 3 ins. long by 4 ft. 3 ins. diameter require 25 h.p. They consume 2·89 lbs. of flint pebbles per ton of ore crushed at stamps. They are run at 27 r.p.m.

Chilian Mills.

Chilian mills are employed either for crushing preliminary to amalgamation, in which case the gold is partly amalgamated in the mill itself, or they are used in lieu of the tube mill as fine grinders following the stamps.

For crushing ores for direct amalgamation the so-called slow speed Chilian mills are well adapted. Machines of this type were extensively employed in Russia and Siberia. They are expensive in first cost, but the power, labour, and repair costs are very low. Furthermore they are notable for their simplicity, requiring little close or skilled attention.

The standard type of Chilian mills used in Russia is 7 ft. to 10½ ft. in diameter with 2 runners 5½ to 6½ ft. in diameter, and from 7 to 12 ins. in width. The speed is 11 r.p.m. The discharge is 8 to 10 ins. Feed is about 1 in. and discharge screen slotted. The water is 6·5 to 10·1 times the ore in weight and duty is 16 to 24 tons per 24 hours. The power required is 7 to 12 h.p.

A slow speed Chilian mill was employed in California on hard close quartzose gold ore. It ran at 8 to 10 r.p.m. It had four runners each weighing 1,200 lbs. travelling on a steel die 3 ins. thick with 5 ins. face and 7 ft. outside diameter, 4½ tons of rock in a tank above and sustained by the axles giving additional crushing weight. Twenty tons of ore per 24 hours were crushed with a 4 in. discharge, and 88·1 per cent. extraction obtained, 0·85 per cent. of the ore passed through a 100-mesh screen. One man per shift handled the mill. Cost of ore crushed 6*s.* per ton. Gasoline power was used consuming under heaviest load 2·17 gallons of distillate per hour. (*A. McLaren.*)

Rapid-running Chilian mills were used as fine grinders after the stamps in the Goldfield Consolidated mill in Nevada on fairly soft ore. There 140 stamps were in operation and six 6 ft. Chilian mills crushing from 4-mesh to 16-mesh were installed. These were operated at 32 r.p.m. Their capacity was 75 tons per 24 hours and the power required 35 h.p. each. The cost of crushing by these mills is given at 5*d.* per ton of ore milled. (*J. W. Hutchinson.*)

At Cripple Creek a 6-ft. Chilian mill running at 33 r.p.m. reduces 4 tons of ore per hour, 60 per cent. of which will pass a 150-mesh screen. The feed passed a ⅜-in. aperture.

Chilian mills are rarely used to-day.

Rolls.

Where a relatively small tonnage is to be crushed coarse, as for example when coarse concentration is employed or where the ore is porous and is cyanided coarse, it is the practice to use rolls. They are cheaper than gravity-stamps in first cost, repairs, labour and power, and are not complicated by screens.

In South Dakota the ore, a hard, close-grained Cambrian quartzite, carrying from 5 dwts. to 7 dwts. per ton, is crushed by rolls. The ore is fed to two 16- by 36-in. rolls used as cracking rolls and two others of the same size are used as finishing rolls. The final product goes through a ¼-in. mesh direct to the cyaniding vats. The rolls require 100 h.p. The milling and cyaniding cost is 2*s.* 2*d.* per ton and 14,800 tons of ore are treated monthly.

Ball Mills.

Krupp ball mills are used extensively in Kalgoorlie, where 44 are at work. Size No. 5 will crush up to 45 tons of ore per day consuming 25 h.p. No. 8 will crush 90 tons per day requiring 50 to 60 h.p. About 45 per cent. of the product from a 25-mesh screen will pass 150-mesh. It is charged with 1 or 2 tons of steel balls and revolves from 21 to 25 times per minute. They work well on either wet or dry ores. The wear and tear of liners, hunch and scoop plates cost 4·64*d.* per ton milled.

Ball mills are used extensively in connection with cyaniding.

Milling Costs.

The following are the milling costs of different stamp mills :—

Mill.	Stamps.	Tons Crushed Monthly.	Cost of Milling per ton.	Rate of Wages per day.	Remarks.
Tonopah, U.S.A.	100	15,000	12*s.*	18*s.*	Silver Gold ore
Goldfield Con., U.S.A.	140	29,500	9*s.*	18*s.*	
Ivanhoe	100	16,600	8*s.* 9*d.*	12*s.* to 14*s.*	Bromo-cyanide treatment of slimes
Oroya Brownhill	50	8,950	17*s.*	12*s.* to 14*s.*	
Gt. Boulder	—	14,800	12*s.* 4*d.*	12*s.* to 14*s.*	Dry crushing with Griffin mills. Roasting.
Melones, Cal.	100	12,000	1*s.* 1½*d.*	10*s.*	Cheap power, labour and supplies
New Unified (Rand)	—	10,000	1*s.* 4*d.*	—	Milling only
Simmer East	—	—	2*s.* 6*d.*	—	

On the Rand, cost of milling of those companies using tube mills varies from 4*s.* 10*d.* to 8*s.* 8*d.* per ton of ore.

In California, with free milling ores and cheap water power, milling costs average from 2*s.* to 4*s.* per ton. In Alaska, with large tonnages of soft, free milling ore treated daily and no cyaniding or fine grinding the costs are about 1*s.* per ton of ore.

Horse-Power per Ton of Ore Treated per Day.

Type of Mill.	Mesh.	Horse-power.
Stamps and vanners	20 to 40	0·75 to 1·0
Coarse concentration	10 to 20	0·5 to 0·8
Combination-stamp	16 to 30	1·5 to 1·75
Chloridising stamp (dry)	to 16	2·0 to 2·5
Chloridising stamp (wet)	to 40	4·0 to 4·5
Magnetic separator	—	0·25 to 0·5
Cyanidation (dry) roll-crushing	20 to 30	0·5 to 0·8
Cyanidation (wet), stamp crushing and sliming	to 80	0·75 to 1·5

(*J. A. Barr*, 'Testing for Metallurgical Processes.')

Standards Adopted by the Institution of Mining and Metallurgy.

1 ton = 2,000 lbs. (avoirdupois).
1 miner's inch = a flow of 1½ cubic ft. of water per minute.
1 sluice head = " 60 " "
1 gallon of water = 10 lbs. at 34°.

Temperatures are to be expressed in degrees centigrade.

Screen apertures and diameters of wire are equal, giving 25 per cent. screening area.

GOLD AND SILVER TABLES.

It is the practice of Continental and South American engineers to report the values of ore in grammes per metric ton. English engineers generally employ the method of quoting values in grs. and dwts., in some cases per long ton of 2,240 lbs., in others per short ton of 2,000 lbs.

TABLE for Conversion of Grammes per Metric Ton into Dwts, etc., per Long and Short Ton.

Grammes per Metric Ton.	Per Short Ton.		Per Statute Ton.		Grammes per Metric Ton.	Per Short Ton.		Per Statute Ton.	
	Dwts.	Grs.	Dwts.	Grs.		Dwts.	Grs.	Dwts.	Grs.

Alluvial or Placer Mining.

Deposits of auriferous or tin-bearing alluvial gravels are termed placers, alluvial drifts, or more simply alluvials. They are classified as shallow or superficial and deep-lying, sometimes called deep leads. Deep leads are accumulations of gravel from extinct or ancient rivers. They are mostly capped by igneous flows, as in California and Australia, though sometimes they may be buried under recent gravels or drift, as at Lightning Creek, B.C., and the Lena Goldfields in Siberia.

The methods of mining used to exploit deposits of this character resemble pillar and stall in some cases and long wall in others. In California the gravel beds can be attacked by means of adits which also serve as drains for the large amount of water present. When the topography of the ground permits adits being used, the cost of mining is low, as at the Hidden Treasure, California, where the costs average 4*s*. 6*d*. per cub. yd. of gravel washed. In the Deep Leads of Victoria, where the pumping charges were unusually large (eleven million gallons per day being raised from one mine), the total cost per cub. yd. was 12*s*. to 15*s*. At the Lena Goldfields the total cost was from 20*s*. to 30*s*. per cubic yard of gravel washed—i.e. when worked by the Lena Gold Fields Company, but it has been for some years under Soviet control.

Superficial Deposits.—All gravel under 60 feet in thickness may be termed shallow or superficial gravels. Surface gravels are worked by the following methods :—

Panning.—A miner can pan ½ cub. yd. to 1 cub. yd. of gravel per 10-hour shift, depending on character of ground and nearness to water; 100 pans per day is a good day's work. Gravel in place is usually estimated at 3,000 lbs. per cub. yd., and the standard sheet iron pan 16 ins. diam. at top and 10½ ins. diam. at bottom will hold 20 lbs.; 150 pans full will make a cub. yd. of dirt.

Rocker.—A man can rock ordinarily from 2 to 3 cubic yards of gravel per day, and save, in practical mining, 90 per cent. of the gold. In alluvial examinations the rocker plays a most important role, and is used in conjunction with the pan for determining the gold contents of any parcel of gravel. When used for this purpose, the design of the rocker differs slightly from that of the ordinary miner's rocker. A well-designed rocker, carefully employed, should save practically all the gold. The plans of most rockers, as published from time to time, are those of the ordinary mining rocker, which is too short, and set on too great a grade for use in saving fine gold. If much fine gold is present in the gravel, it will be advisable to use a strip of common Brussels carpet, laid along the floor of the rocker. This carpet is held in place by cleats and so can be easily removed in cleaning up.

Long Tom or short sluice can handle 3 to 10 cub. yds. of dirt per day, depending on the amount of water available and the character of the dirt.

Hand Sluicing.—Capacity of a sluice box depends upon the amount of water, grade of sluice. deposition of tailings, and character of gravel. No capacity can be given. Grade of sluice varies from 2 ins. to 21 ins. per box (12 ft.). An ordinary sluice box is made from 2-in. planks and is 12 ins. wide by 12 ft. long.

Grade and Duty of Sluices.

Grade and Duty of Sluices.—The relation of actual width to the best ratio of quantity may not be very significant, but there is a notable increase in efficiency in passing from the smallest widths to the larger, and boxes less than 1 ft. wide are to be avoided, especially if the gravel is coarse. Treating 30- to 40-mesh sand on a 1 per cent. grade (say 1¼ in. per 12 ft. box), one sluice head of water requires a channel 2 ft. wide to enable it to attain maximum duty. On a 2 per cent. grade, half a sluice head requires 2 ft. of width, the quantity of water required for maximum duty with a fixed width diminishing with increasing grade, but at what rate there are insufficient data to determine. Apparently the best width required for constant quantity of water varies directly as the grade. Coarser material requires a greater depth of water, and for 4 to 6 mesh gravel on a 2 per cent. grade, 1 ft. of width per sluice head is indicated. Variations up to 50 per cent. in the water make little difference to its duty, consequently the actual position of the optimum is not easily determined. Naturally the capacity of the sluice itself is correspondingly varied, and the mode of transportation and the saving are doubtless affected in any case.

The rate at which duty varies with slope is the resultant of so many variables that no law can be stated for all cases. In the neighbourhood of the best conditions the Utah experiments support the approximate rule that duty (water, width, and material being constant) varies as the 1·75th power of the grade. A single experiment with natural gravel on low grades by the U.S. Geol. Survey gave the 1·84th power. (*R. T. Hancock.*)

Good modern practice provides about 1 ft. of sluice-box width for every 2 cub. yds. of average material treated per hour, and 3,000 gallons of water per cub. yd. treated on a grade of 6 ins. to 12 ft.

Besides the ordinary feeding of sluice-box by means of hand shovelling, many modified methods of feeding and disposing of tailings are employed. In Russia and Siberia the favourite method in use is to transport the gravel to and from the sluice box (here greatly modified from the plain open sluice-box) by the employment of horses and small carts. This is a most expensive system and the yardage treated is small. Other variations are: the use of wheelbarrows, tramming by cars, handling gravel by means of derricks, digging gravels by means of steam shovels, and loading into cars or direct into sluice, feeding sluice by means of scrapers operated by horses or steam power (drag-line scrapers).

The methods of preventing accumulation of tailings are to deposit them in running water or to remove them by means of drags, belt or link elevators, or hydraulic elevators.

HYDRAULIC MINING.

Hydraulicing proper is the method of mining by which jets of water under high pressure are thrown against a gravel bank, thereby undermining the gravel, which falls and is carried by the current into the sluice. The necessary pressure is obtained either by natural means, *i.e.* by conveying the water from some source having a greater elevation than the working face, or by pumping directly into the supply pipe by powerful pumps. In the former case water is conveyed to the working by means of pipes, flumes or ditches. Ditches are generally most convenient and economical for conveying water for long distances, but sometimes the nature of the ground is such (either too porous or too rocky and difficult to excavate) that a flume becomes cheaper. When lumber is abundant wooden flumes are built, but in many cases, especially in the tropics, where wood rots rapidly, sheet steel flumes are preferable. Steel flume per foot, including rivets, angle iron, etc., ready for transport, costs from 4*s.* to 1*l.*; the sizes vary from a cross-section of 1·28 sq. ft. to 20-48 sq. ft. From the ditch or flume the water is fed through a strainer into a pressure box. From here, a pipe leads to the Y's, which in turn lead to the monitors or giants.

Monitors or Giants.

Monitors or Giants.—These are appliances consisting of a base for attachment to the pipe line and a long conical reducing piece, arranged with one or more joints so that it can be rotated in any direction horizontally and through a very wide angle vertically. The smaller or conical end is fitted with a nozzle butt to which different sizes of nozzles may be attached as circumstances may require. Modern giants are fitted with deflectors, attachments on the butts whereby the giant is turned or deflected by means of the force of the water itself. The high-pressure giants also have ball-bearing joints.

Nozzles from 2 ins. up to 10 ins. are used, working under heads or pressure from 100 up to 600 ft. or more.

The amount of gravel which can be washed down will depend upon its nature, upon the volume and pressure of the stream of water issuing from the nozzle, and is also dependent in no small degree upon the skill of the operator who handles the giant.

The following gives the approximate amount of gravel washed under various heads:—

Effective Head in Feet.	Size of Nozzle.	Flow in Cub. Ft. per Minute.	Approximate amount of Gravel in 24 hours in Cub. Yds.	Weight of Giant. Lbs.	Price of Double Jointed Ball Bearing Giant. £
100	2 ins.	104·88	160	120	28
200		148·32	230		
300		181·61	280		
400		209·82	320		
100	4 ins.	420·06	650	225	55
200		594·00	930		
300		727·56	1,130		
400		840·12	1,300		
100	6 ins.	944·58	1,460	335	66
200		1335·72	2,000		
300		1634·08	2,540		
400		1889·16	2,920

200		3711	5,760		
300		4545	7,050		
400		5248	8,140		

(*Hendry.*)

Hydraulic Monitors and Pelton Wheel Jets.

J. J. Garrard (*Trans. I.M.M.* 1917) gives a table of discharges in cubic feet per minute for different sizes of nozzles and various heads derived from the formula: Delivery in cub. ft. per min. $= 3{\cdot}75\, d^2\sqrt{P}$, where $d =$ diameter of nozzle opening in ins. and $P =$ gauge pressure in lbs. per sq. in., or effective head $\times 0{\cdot}4326$. An equivalent formula given by him is $2{\cdot}468\, d^2\sqrt{h}$, where h = effective head in ft. The factor 2·468 allows for a nozzle contraction coefficient of 0·94, whereas Hendry's figures in the above table are based on the theoretical value 2·624, and make no such allowance.

Costs.

The costs per cub. yd. were at North Bloomfield 2·05*d.* per cub. yd. and at La Grange 3*d.*

In British Columbia one and a half million cub. yds. were mined and washed at a working cost of 0·97*d.*

In Northern California placer ground containing only 1·26*d.* per cub. yd. has been profitably worked. The amount of gravel washed was 1,251,399 cub. yds., yielding 6,330*l.* The profit obtained was 821*l.*

Hydraulic and other Elevators.

When a hydraulic mine possesses an insufficient slope of bed rock for moving material (the lightest grade permissible being 220 ft. to the mile) other methods of disposing of the gravel 'piped' must be employed. Where water under pressure is cheap and abundant, hydraulic elevators are employed. They are of the pipe type—either Hendry, Evans or Campbell and the Giant Elevator.

The pipe elevator operates on the principle of an injector. Water under pressure is discharged through a nozzle set within a steel jacket, creating a vacuum, and causing water and sand and gravel fed into intake to rise to a height corresponding to 10 per cent. of the head under which the water is applied.

Three sizes are made: 10-inch throat 3½–4½ inch nozzle, using 300 to 500 ins. of water; 12 inch throat 4½–5-inch nozzle, 500 to 750 ins. of water; 15-in. throat, 750 to 1,000 ins. They weigh about a ton and cost 250*l.*

In South Oregon, U.S.A., at the Weimer placer mine, two hydraulic elevators are employed to handle the gravels. One of them has a lift of 39 ft., and operating with a head of 330 ft., uses 11 cub. ft. of water per sec., besides taking all water from two No. 2 Giants. The second elevator has a lift of 9 ft., a head of 125, and uses 18 cub. ft. of water per sec., besides all the water from the first elevator. This makes a final discharge of 40 cub. ft. per sec.

Giant Elevators.

Besides undermining and cutting the gravel it has been discovered that gravel can be effectively 'driven' up a slope or incline to a raised line of sluices by means of the power of water under pressure. An elevator based on this principle is termed a 'stacker.'

In California a stacker was operated as follows: A chute was built sloping upwards at 30°. This was 4 ft. wide by 24 ft. long and constructed of 1½-inch planks. Riffles 2 ins. apart and with a drop of 2½ ins. between were laid across the bottom. These were covered by an iron grizzly. At the foot of this chute a 3-foot sump was dug in which was set up a hydraulic elevator with a 12-inch throat and worked by a 5-inch giant. This elevator, working under a 90-foot head, elevated to 16 ft. vertically the seepage, fine and water from two field-giants.

Twenty feet in front of the stacker was installed the 3-inch drive giant. Two 4-inch field-giants wash the gravel to the chute and the drive giant forces it up the stack, the fine material falling through the grizzly and down the riffles to the elevator, which raises it to the sluice-boxes.

The field-giants handled 600 cub. yds. per 24 hours, and the gravel could easily be raised to 25 ft. vertically by means of the drive giant. The cost of handling material exclusive of equipment was under 2½*d*. per cub. yd. (*S. S. Smith.*)

Ruble Elevator.

The Ruble elevator is constructed on the above principle, but it is more portable and does away with the hydraulic elevator. It is also self-contained, as the sluice-box is part of the machine.

In Idaho, U.S.A., this elevator has been tried with excellent results (*see* Porter, T.A.I.M.E., 1909, for a detailed description of this elevator). The following points are claimed to its merit: 1. It handles larger rocks with less water than other types of elevators. Handles boulders up to 1 ton in weight. 2. It dispenses with the boulder crew, either at the mine, ground, sluice-box or dump. 3. It saves the gold and the gold-saving department may be protected by lock and key. 4. The gravel is picked up in close proximity to the giants, the gold immediately extracted, and the boulders and other waste material dropped back on bedrock previously worked off, instead of being transported a long distance to the dump. It makes its own dump.

Mechanical Elevator.

In regions where water is neither cheap nor abundant, in handling gravel or tailings, resort must be had to some form of mechanical elevators. A mechanical elevator was erected some years ago on Bonanza Creek, Alaska. This was made of a frame of steel, 49 ft. high, mounted on wheels. The gravel was elevated by a bucket line of the close-connected type, 76 buckets in all, each with a capacity of 3 cub. ft. These discharged at a rate of 26 per min. directly into a sluice-box. The pit was drained by means of a 12-inch centrifugal pump, assisted by a hydraulic jet. The power was 200 h.p. in all, 35 for the bucket line and 165–175 for the pumps. The actual capacity per day was 1,500 yds. (*T. A. Rickard*). The first cost of this machine was high, and in actual running it proved costly in operation and repairs. Another machine of the same type, but employing a heavy dredge bucket, was erected in Eastern Canada.

Centrifugal Pumps.

Centrifugal Pumps as a means of elevating gravel and tailings have been extensively employed in Australia. It is claimed that with wood fuel at 7*s*. per ton of 50 cub. ft. and European rate of wages paid, to elevate tailings with pumps should not cost more than 2½*d*. per cub. yd. of solid. Thompson & Co., of Victoria, are the makers of gravel pumps suitable for this class of work. Their pumps vary in size from 3½ ins. to 16 ins. The capacity of solids per hour from 7 to 150 cub. yds. The indicated horse-power from 2½ to 583. The combined suction and delivery head from 10 feet to 100. An installation of this kind possesses the advantage of being cheaper to erect and easier to move than the belt or bucket type of elevators mentioned. However, where there is an undue amount of large stones present in the gravel, the latter type is preferable.

Pipe Lining.

Three rubber-lined pipes, each of 9 in. internal diameter and length of about 20 ft., have been in continuous operation on the discharge line from an 8-in. gravel pump at the Sungei Besi Mine, Malaya, for a period ranging from 18 months from the date of installation of the first pipe. These pipes have been subjected to a continuous flow of gravel, amounting to about 17,000 cub. yds. of solids per month, and a working pressure of about 17 lb. per sq. in. The three pipes, although differing somewhat in design, are all alike regarding the successful results of the rubber applied to them, there being little or no evidence of wear or abrasion on the rubber after this lengthy period of operation. The lining is of crepe rubber about ½ in. thick. The life of a lap-welded mild steel pipe $\frac{5}{16}$ in. thick on the same line, with frequent turning to ensure even wear, does not amount to an average of seven months. ('*Mechanical World*,' Jan. 21, 1927.)

See also 'The Use of Rubber in the Mining Industry,' by H. P. Stevens and F. B. Powell, *Trans. Inst. Min. Met.*, vol. xxxvi. (1926–27), p. 263.

Dredging for Alluvial Minerals.

(Contributed by Harold E. Fletcher, A.I.N.A., M.I.Mar.E.)

The most important form of alluvial mining is dredging, for the recovery of gold, platinum, and tin. The greater part of the platinum recovered in Siberia and Russia is by dredging, and that of the tin in the Malay States. When all conditions requisite for successful working are present, when the ground has been properly proved * and a well-designed and effective dredge installed, then this type of mining is the safest and surest of all forms of mining investment.

Careful systematic boring is necessary to get true values. Dredging properties call for certain conditions, and unless these exist the success of the enterprise suffers. The conditions are:

(1) The presence of the mineral, which should be evenly distributed throughout the pay dirt.
(2) Sufficient ground to warrant the installation of at least one dredge.
(3) Soft bedrock, free from pinnacles.
(4) Absence of large boulders.
(5) Absence of permanently frozen ground.
(6) Absence of great amount of clay.
(7) Absence of heavy floods.
(8) Surface of an even contour, not too rough and broken.
(9) The ground should retain sufficient water to float dredge (50 miner's ins.), or available water supply from a river.
(10) The economic conditions, *i.e.* labour, transport, climate, vary inversely with amount of mineral in ground.

The life of a well-designed dredge may be calculated at from twelve to fifteen years, provided it is kept in good repair. Repairs for the first three years would be normal (excepting accidents), such as the replacing of bucket pins and bushes, ladder roller spindles and bushes, screen plates, tumbler bearings, and usual power plant replacements, and later on in the life of the plant tumblers and shafts, main gears, buckets, repairs to pontoon, etc.

Broad flood plains or ancient lake gravels form more suitable dredging ground than does deposit situated in narrow rocky gulches. Frozen ground cannot be dredged without preliminary thawing. Dredging of gravels lying in rapid rivers is risky, as there is always danger of losing the dredge by sudden floods. Gravels from 10 to 80 ft. below water and 20 ft. above have been successfully dredged.

The modern dredge consists of a hull or pontoon of wood or steel, upon which is mounted the digging device, a bucket ladder capable of being raised and lowered, the washing plant comprising screen, tables or launders, the pump of the centrifugal type for water supply to screen and tables, the stacker or elevator to dispose of the tailings well astern of the dredge, and the power plant. The buckets raise the ground and discharge into the revolving perforated screen, the fines pass through the perforations on to the tables, and the stones and large material pass through the screen to the tail chute and on to the tailings stacker. The dredge can cut its own passage. The cutting depth and manœuvring lines are worked by special multi-barrelled winches, controlled by one man, the winchman.

'Suction' dredges are used at times; they are only successful in light and free ground with level bedrock. The power required has been found to exceed that of the bucket dredge of equal output. With the suction dredge it has been found difficult to control the surges of water that sweep the tables when the spoil will not draw easily. This type of dredge has not given good results on tin in the Straits of Malaya.

'Bucket' dredges are classified in two types, the New Zealand and the American; the latter has been evolved from the former to suit conditions existing in California and other parts. The principle is the same, but the American type is associated with heavier construction, larger buckets of the close-connected type instead of open, spuds (adjustable piles) instead of a headline, the raised pilot (or central control) house, and other modifications. Both types have their advocates and both their utility.

The New Zealand type was associated with open-connected buckets, moderate power, simple engine for driving all units and light construction, but to-day this type is built of fairly large capacity and heavier construction. In its smaller sizes for lighter ground its first cost is in its favour, also for prospecting work or proving a dredging property; also where difficulties of transport prevent the use of the heavier type of dredge.

Transport.—Dredges are generally shipped in pieces for re-erection, the steel pontoons being riveted and launched at site. The heaviest parts to transport are the main engine castings, the boiler shell, the tumbler castings (mostly steel), crown wheel castings, winch barrels, screen ends, etc. The 'Tumblers' weigh from 15 cwts. in the small to 15 tons in the large sizes; boilers stripped, from 3 to 10 tons; watertube boilers, the heaviest part being the steam drum, from 7 to 60 cwts. See 'Air Transportation of Gold Dredges in New Guinea,' by C. A. Banks, *Bull. Inst. Min. Met.*, August 1932, No. 335.

Hulls.—These have to be strongly designed to stand the stresses. Wood pontoons are not entirely satisfactory and generally have to be replaced during the life of the machinery; they suffer damage by ice in cold countries, and are difficult to build to stand stresses, and much heavier than steel.

* See *Alluvial Prospecting*, by C. Raeburn and H. B. Milner. 1927. Also 'The Valuation of Alluvial Deposits,' by W. R. Rumbold, *Trans. Inst. Min. Met.*, vol. xxxvii. (1927-28), p. 437.

Power.—Where wood and coal are plentiful, steam is cheapest. In Malaya the Rawang coal (8,000 B.Th.U.) is used in water-tube boilers with chain grate stokers; steam pressure 160 lbs., and 100° superheat. Where oil is available at reasonable cost, it can be burnt under boilers or used in Diesel or semi-Diesel engines, and these have proved more economical than steam.

A gold dredge with 9 cu. ft. close-connected buckets is running in South America with semi-Diesel engines, also smaller dredges in Burma, etc. Full Diesel engines require the services of a specially skilled engineer. Several of the recent tin dredges have Diesel-electric generating plant on board running electric motors. Producer-gas plant and engines are used in Burma, Malaya, Africa, etc., running on charcoal, driving direct or driving generators to supply current to the several motors. Where electric current is available and power can be transmitted to the dredge by cable at reasonable cost, and transformed on the dredge to the required voltage, it is in favour of low running costs, but it is generally accepted that it does not pay to build a special generating plant unless the ground will carry four or more dredges. Waterfall power to generate current is also being used.

The horse-power installed on gold and platinum dredges varies according to the capacity of bucket, dredging depth, etc. The distribution of power is generally as follows:

Bucket chain . . .	33% of total power.	Screen . . .	10% of total power.
Water-pump . . .	30% ,, ,,	Elevator . . .	12% ,, ,,
Winch . . .	15% ,, ,,		

On tin dredges, where larger water supply is necessary and higher water pressure, the pump power proportion is larger. On large dredges a separate winch is often fitted to deal with the bucket ladder.

Gold Dredges.

Larger types of American design are used in America, Siberia, etc., in addition to the open-connected type. Gold is saved on tables covered with cocoanut matting and expanded metal; the gold by reason of its heavy specific gravity settles in the mats, the dirt being washed down the tables overboard, the mats being taken up at periods and washed. With properly designed tables and adjustable water supply, quite fine gold can be saved. Platinum is easier to save owing to its higher specific gravity.

Tin Dredges.

The main difficulty is not in raising the ground, but in treating it efficiently; the tables require to be of large area and the water supply larger than for gold dredging. Tables or 'launders' are genearlly from 3 to 4 ft. wide and up to 80 and 100 ft. long, wood riffles are fitted, and the wash agitated gently by hand-raking or mechanical means to allow the tin to sink through the wash and settle on the bottom of the launders. Owing to the large area of the tables the pontoons are of larger dimensions than for gold dredges; tables up to 7,000 to 8,000 sq. ft. area in two tiers are in use. Owing to the difficulty of carrying such tables, some of the latest dredges have been designed with jigs and classifiers, or a combination of riffles, launders, jigs, and classifiers, which will allow of better treatment and the saving of finer tin. The use of jigs allows of better saving adjustment. With skilled attention, up to 92 per cent. of the boring values have been obtained. Clay in the ground in both gold and tin dredging presents great difficulty to the dredge designer, and to break it up and release the values it contains call for special arrangements, such as puddlers, high-water pressure, etc.

Where large boulders or heavy clay is met with a 'tray' connected bucket chain is sometimes used, the trays being castings equal to the base of the buckets and contributing in output each about 25 per cent. to 30 per cent. of the bucket capacity.

The design for tin dredges is tending towards the American type in regard to the design of the driving gear, buckets, tumblers, winches, etc. The latest dredges have close-connected buckets of cast manganese steel and nickel-chrome steel pins, cast manganese tumblers, etc.

There has been a vast amount of capital put into tin dredging in the Malay States and Siam, the number of dredging plants reaching towards 200. Some of these companies have paid 25 per cent. dividend for a number of years.

The largest English-built dredges have close-connected buckets of 12 cu. ft. capacity, a large proportion 8 and 9 cu. ft. The open-connected dredges range from 6 to 15 cu. ft. buckets. Dredging depth ranges from 30 to 80 ft., and dredges have been built to dig 120 ft.

Output varies according to bucket capacity and the rate at which the ground can be efficiently treated. The open-connected bucket is run from 14 per minute for the smaller to 12 per minute in the larger sizes. The close-connected bucket from 28 to 18 per minute.

Maximum output is calculated:

$B \times S \times 60 \div 27 =$ cu. yds. max. per hour. $S =$ number of buckets delivering per minute.
$B =$ capacity of buckets in cu. ft. $27 =$ number of feet per cubic yard.

Roughly, 1 cu. yd. is calculated $1\frac{1}{2}$ tons.

To obtain the estimated output, one-third is deducted from the maximum, but this is not always reached; buried timber and large boulders tend to decrease output. The removal of barren overburden (to reach pay dirt) and difficulties of cleaning up bedrock lessen the profitable dredging time. A further factor is time lost in cleaning up the tables or launders to recover the gold or tin. Working time varies: many dredges have averaged over 600 hours per month.

Working costs vary with difficulties of ground, cost of fuel, and labour.

Comprised in above are European and native labour, fuel, stores, spares, camp upkeep, passage money and leave pay, management expenses, depreciation of plant, insurance.

The aggregate cost of running a small dredge does not vary greatly from running a larger one and ground that is too low in value to give a return on a small dredge could be made to pay with a dredge of large output. With favourable conditions, dredges on easy ground have been run for as low as 1·5*d.* per cu. yd. treated. Large tin dredges in Malay 3·13*d.* to 4·0*d.* per cu. yd. treated.

TIN DREDGES.

Bucket Cap.	Type.	Monthly Output in cu. yds.	Working Hours per Month.	Dredging Depth.	Pontoon.	Steam. H.P.	Net Weight.
Cu. Ft.				Ft.	Ft. Ft.		Tons.
10	Open-con.	57,350	592	50	150 × 34	250	500
11	,,	89,000	550	50	150 × 40	320	700
12	,,	85,000	560	60	165 × 42	375	750
13	,,	78,000	—	60	165 × 45	380	820
15	,,	99,000	600	35	140 × 46	*400	—
5½	Close-con.	89,000	651	45	150 × 45	320	900
6	,,	Est. 90,000	600	50	155 × 45	375	—
8	,,	,, 120,000	,,	60	160 × 46	400	1,200
9	,,	,, 130,000	,,	60	170 × 52	450	1,300
12	,,	,, 150,000	,,	60	180 × 52	500	1,600

* Gas engines.

The difference in output is due to difficulties in working the ground.

MALAY TIN BASIS.

1 Kati = 1⅓ lbs. 100 Katis = 1 Picul = 133⅓ lbs.
16·8 Piculs = 1 ton. Straits Dollar = 2*s.* 4*d.*
Value of tin in ground varies from 0·33 to 2·0 Kati.
Native labour costs 1*s* 9*d.* to 2*s.* 3*d.* per day. Engineers, 4*s.* 6*d.* to 5*s.* per day.
Native coal, 24*s.* per ton. Wood, 25*s.*
Fuel oil, 90*s.* per ton. In bulk, about 82*s.*

See 'Suction-Cutter Dredging for Tin in Malaya,' G. A. More. Some Notes on Malayan Bucket Dredges,' E. J. Vallentine, *Bull. Inst. M. M.*, Dec., 1929.

NEW ZEALAND TYPE DREDGERS (GOLD).

Size of Buckets.	Estimated Capacity. In cu. yds. Monthly.	Digging Depth below Water-Line	Weight including Hull.	Price, f.o.b. London	Horse Power.
Cu. Ft.		Ft.	Tons.	£	
3	30,000	20	100	5,000	35
4	40,000	20	180	9,000	—
5	50,000	26	220	13,000	56
6	60,000	40	280	16,000	—
7	74,000	32	350	20,000	180

The Californian or American dredge is costly, very heavily built, with close-connected buckets digs with spuds, and till lately built with wooden hulls.

For properties where the transport is high, as in parts of Siberia, and where heavy repairs are difficult, a well-built New Zealand type of dredge, with ample stock of spares, is preferable

Indeed, its choice is imperative in some cases, for the high transport costs to some properties exclude the use of the ponderous American type of dredge. On the other hand, cheap transport, access to machine shops, and with heavy or stiff-cemented gravel, or large deep deposit of fair digging gravel (the latter permitting the handling of enormous daily yardages) are conditions favourable to the use of the American dredge.

CALIFORNIAN TYPE DREDGERS (GOLD)

Size of Buckets.	Estimated Capacity per month. In cu. yds.	Digging Depth below Water-Line.	Weight exclusive of Hull.	Price Erected.	Horse Power.
Cu. Ft.		Ft.	Tons.	£	
3	45,000– 60,000	36	350	22,000	180
5	90,000–110,000	36	520	30,000	220
7	110,000–150,000	35	576	34,000	300
8½	150,000–185,000	48	1,000	65,000	560*
13	250,000–280,000	40	1,100	90,000	415

* This includes 100 h.p. for pump for two monitors or giants.

SECTION XXXIX

PART II

MINERAL VALUATION.

(Revised and brought up to date by Sir Richard A. S. Redmayne, K.C.B., M.Sc., M.I.C.E., M.I.M.M., F.G.S., etc)

In all mine valuations for sale, probate or other purposes, it is necessary to ascertain the quantity and value of the product being mined, or to be mined. In the case of metalliferous mines especially, the determination of the average ore content is of the highest importance both in respect of the visible and the prospective resources, and demands the exercise of the highest qualities of expert knowledge and experience on the part of the valuer, for the prospective value depends on the probable extension of the mineral deposit in depth and laterally, in regard to which such questions as the origin and structural character of the deposit, secondary enrichment, development in neighbouring mines and depth of exhaustion enter largely into consideration.

Before the ascertainment of the value of a metalliferous mine can be made, a complete and detailed sampling of the deposit being worked must be carried out. The process is an arduous and expensive undertaking, and, in the case of an extensive mine, may well absorb many weeks before completion.

In the taking of samples the interval to be allowed between samples is of importance. If the ore is fairly regular in width and value an interval of 10 ft. will usually suffice. If spotty in value and subject to sudden changes, a lesser interval must be allowed, even as low as 3 ft. in some cases. If the vein is built up of common sulphides, such as pyrite or galene, variations are apt to be small and 20 ft. would not be an unsafe distance to take. The sample is obtained by cutting a groove across the entire width of the lode. As a sampling plan must be made it is necessary to measure as regularly as possible along the workings and mark each sampling site with coloured chalk. A sketch of each section of the working in which the sample is taken should be made, showing thereon variations in the vein (lode), the number of each sample and its position, and any other helpful information. The correct labelling of samples and the sacking and sealing of the samples, and the careful removal of them to a safe place are matters of importance.

An accurate sample represents a true cross section of the ore body. In the calculations, not the arithmetical but the geometrical mean must be arrived at. To give an example (Rickard):—

Width in Ft.	Assay Ozs. of Gold Per Ton.
4 ft. 4 in.	2·35
6 ft. 2 in.	0·45
7 ft. 5 in.	0·62
4 ft. 9 in.	0·85
2 ft. 5 in.	1·02
3 ft. 6 in.	2·40
2 ft. 5 in.	4·25
0 ft. 8 in.	5·20
1 ft. 2 in.	4·65
2 ft. 2 in.	3·21
35 ft. 0 in.	25·00

Now the arithmetical mean yields 3½ ft. of ore averaging 2½ ozs. of gold per ton, which is the wrong method of ascertainment. The correct figure is arrived at by taking the sum of the widths in each case multiplied by the ozs. per ton per ft. width and dividing this total by 35, which gives the geometrical mean of 1·71 ozs. per ton.

In carrying out the estimate of values, the term 'ore in sight' is frequently used when alluding to the ore reserves, but a better definition is that of Mr. Philip Argall, viz.:

'*Ore developed*'—which is ore absolutely without variation, ore exposed on all sides.

'*Ore being developed.*'—First class blocks with one side hidden; second class with two sides hidden; third class blocks with three sides hidden.

'*Ore expectant.*'—The prospective value of a mine, beyond or below the last visible ore, based on the fullest possible data (clearly set forth) from the mine being examined, and from the characteristics of the mining district.

In the case of coal mines and most stratified mineral deposits, owing to the more or less uniformity of the composition of the material mined, the question of sampling is of minor importance and may not even arise at all.

In considering the value of a mine as between a willing seller and a willing purchaser, or for the purposes of probate, having to estimate the amount of the annual profits which may be derivable from the mine and the period over which they will be forthcoming, one has to determine the present value of the annuities so arrived at. For which purpose various formulae are in use. In 1940 there was published by the *Iron and Coal Trades Review*, 'Formulae for use in connection with the Valuation of Mineral Properties,' for use by the valuers engaged in the work of valuing the coal royalties of Great Britain for acquisition by the State. The work of Mr. H. W. Naish, M.B.E., A.C.A., of the Coal Commission.

In Mr. Naish's valuable brochure no less than 12 formulae come under consideration, but the present writer has found the first five sufficient to meet most of his needs, namely that which deals with—

(I) Immediate Annuities.

(II) Deferred Annuities.

(2) Where a single period of deferment precedes a single uniform period of enjoyment and the remunerative rate is the same for both periods.

(3) Where a single period of deferment precedes a single uniform period of enjoyment but the remunerative rate in each period is different.

(4) Where there are varying periods of deferment and enjoyment and the remuneration rate is the same throughout.

(5) Where there are varying periods of deferment and enjoyment but the remunerative rates are different.

In all these formulae two rates of interest are employed, namely the 'accumulative,' or low, rate of interest for the recovery of the investor's capital, and the 'remunerative,' 'risk,' or high rate of interest.

Most of these formulae are based upon the same reasoning as those adopted by the present writer in 'The Ownership and Valuation of Mineral Property in the United Kingdom' (Longmans Green & Co., 1920), and used by him in his various valuations of mineral property. He has also made use of Hoskold's Tables, except in the case of deferred annuities with two rates of interest, in which case he has worked out what he believes to be the correct figures for himself.

In addition to the two works alluded to above, the interested reader is referred to Professor H. Louis' work, 'Mineral Valuation' (Charles Griffin, Ltd., 1920), 'The Theory of Finance,' by George King (C. & E. Layton, 1898), the last-named work containing a very thorough exposition of the doctrine of annuities, 'Principles of Mining Valuation, Organization and Administration,' by H. C. Hoover (London: Hill Publishing Co., Ltd., 1909), and 'Modern Mine Valuation,' by M. Howard Barnham (Chas. Griffin & Co., Ltd., 1912).

THE FORMULAE.

The 'present value' of the annuities (and in the case of a current going mine, plus the present value of the sum the machinery and plant will ultimately realise, or may be put at) is the value of the mine. The 'Purchase price' is, therefore, the sum paid down, and in order that the bargain may be an equitable one, the sum paid down should be such that the purchaser on the exhaustion of the mine or on the expiration of the term for which the lease thereof has to run, shall receive back his original outlay, together with interest per cent. agreed upon.

The formulae which the present writer has always used in valuing mining property are those in which two rates of interest are involved, namely, the interest on the purchase-money together with a return per annum on a part of the purchase money. The *rent* of the annuity in these circumstances consists of two portions—the *remunerative* or high rate of interest (sometimes termed the 'risk rate') and the *accumulative* or low rate of interest—for we create, as it were, a sinking fund to be set aside and separately invested and accumulated at a low rate of interest so as to liquidate the debt or capital and extinguish it suddenly at the end of the period; or we may regard each portion of capital in the successive payments of the annuity to be at once applied towards liquidating the debt, which will then gradually decrease until it finally vanishes, in which case as the debt is being paid off, a less and less proportion of the annuity will be required for interest, and a greater and greater proportion will be available to refund the capital. The two ways of regarding the transaction are the same. The sinking fund may be invested in securities until it amounts to the debt, or it may be invested in the security of the debt itself.

The sinking fund is therefore of the nature of an annuity which must accumulate at interest until it amounts to the original capital.

When it comes to considering the problem of a *deferred* annuity, under conditions in which two rates of interest are involved, authorities are at variance: thus the method adopted by some eminent valuers in the past was to find the value of an immediate annuity at two rates, and discount the value so obtained during the period of deferment at the higher rate, whereas it is not according to the conditions of the problem to use one rate only during the period of deferment.

For the clear mathematical reasoning by which Mr. King arrives at his formula, which is widely accepted as the correct one to use, readers are referred to pp. 38 and 39 of his excellent treatise referred to above. But the doctrine on which his formula is based may briefly be stated thus:

(1) A speculator is throughout the period of waiting or deference, only entitled to interest at a high risk rate on his original invested capital.

(2) During deference the latent interest (or hypothetical dividend) should accumulate at a low rate of compound interest.

The income during a period of enjoyment comprises:

(3) A high risk rate of interest on the original capital only

(4) A low rate of interest upon the accumulation;

(5) The exact extra annual sum required a sinking fund (put out at a low rate of interest) to replace the capital and accumulation at the figure at which it stood at the end of the deference immediately before entering on the annuity.

Mineral properties which fall to be valued may be divided into three different classes, viz.:

(1) Terminal annuities with immediate entrance.

(2) Terminal annuities with entrance deferred.

(3) Lump sums due after a period of deferment.

Valuations of all these rights may be governed by Mr. King's stipulations. Various formulae for the solution of the problems have been invented, some of which are very complicated. Those devised by Mr. Naish are, in my opinion, the simplest and are reproduced below. But for his examples and proofs the reader is referred to his book, in which are given a series of tables also.

I. Immediate Annuities.

$$\text{YP} = \frac{a}{\dfrac{20}{20-x} + \dfrac{a\text{R}}{100}}$$

where YP = Years purchase.

a = The amount to which £1 per annum accumulates during the period of enjoyment of the annuity at r per cent.

R = The remuneration (or high or risk) rate of interest.

r = The low or 'gilt-edged' rate of interest (*i.e.* after deduction of income tax).

x = The rate of income tax in shillings in the £.

II. Deferred Annuities.

(*a*) Where a single period of deferment precedes a single uniform period of enjoyment and the remunerative rate of interest is the same for both periods.

$$\text{YP} = \frac{a}{\dfrac{20}{20-x} + \dfrac{\text{AR}}{100}}$$

here A = The amount to which £1 per annum accumulates during the period covered by the whole transaction (*i.e.* deferment + enjoyment) at r per cent.

(*b*) Where a single period of deferment proceded a single uniform period of enjoyment but the remunerative rate in each period is different.

$$\frac{a}{\dfrac{20}{20-x} + \dfrac{a\text{R}}{100} + \dfrac{bc\text{P}}{100}}$$

here b = The amount to which £1 per annum accumulates during the period of deferment at r per cent.

c = The amount to which £1 accumulates during the period of enjoyment of the annuity at r per cent.

P = The remunerative rate of interest during the period of deferment.

(*c*) Where there are varying periods of deferment and enjoyment and the remunerative rate is the same throughout.

$$\frac{az}{\dfrac{20}{20-x}+\dfrac{AR}{100}}$$

Here the numerator = the sum of the results obtained by multiplying each stage of income by aZ.

d = The period of deferment before a given stage of income.
e = The period of enjoyment of a given stage of income.
t = The period covered by the whole transaction.
z = The amount to which £1 accumulates at r per cent. in $t-(d+e)$ years.

(*d*) Where there are varying periods of deference and enjoyment but the remunerative rates are different.

$$\frac{az}{\dfrac{20}{20-x}+\dfrac{a'R}{100}Z'}$$

here a' = The amount to which £1 per annum accumulates in e' years at r per cent.
d' = The period of deferment before a given remunerative rate rules.
e' = The period during which a given remunerative rate rules.
z' = The amount to which £1 accumulates at r per cent. in $t-(d'+e')$ years.

As this formula has reference to a somewhat involved situation, the following example of a valuation of a coal property may be given in exemplification.

Example.

In this case the coal area, which will not be taken over until the commencement of the 15th year (period of deferment is therefore 15 years), the ' certain ' or ' dead ' rent ruled as follows :—

at the end of the 15th year is £500
" " " " " 16th " " £650
" " " " " 17th " " £750
" " " " " 18th " " £900
" " " " " 19th " " £1,500

and by way of royalty rent—

at the end of the 20th year is £2,500.
and thereafter for 80 years is £3,666 per annum.

The period of revenue of certain rent is 5 years, and 15 + 5 = 20.

The period of revenue from royalty (in which the certain rent merges) is 80, and 80 + 20 = 100 the total period of the transaction. Then the values of z and z' are respectively as follows :—

$$\begin{aligned}
&\text{Value of } z = t-(d+e)\\
&\text{and of } z' = t-(d'+e')\\
(1)\ & 100-(15+1) = 84 = z\\
& 100-(15+5) = 80 = z'\\
(2)\ & 100-(16+1) = 83 = z\\
& 100-(15+5) = 80 = z'\\
(3)\ & 100-(17+1) = 82 = z\\
& 100-(15+5) = 80 = z'\\
(4)\ & 100-(18+1) = 81 = z\\
& 100-(15+5) = 80 = z'\\
(5)\ & 100-(19+1) = 80 = z\\
& 100-(15+5) = 80 = z'\\
(6)\ & 100-(18+1) = 80 = z\\
& 100-(20+80) = 0 = z'\\
(7)\ & 100-(20+79) = 1 = z\\
& 100-(20+80) = 0 = z'
\end{aligned}$$

Now, owing to the rent derivable from the property during the first 5 years being in the nature of a ' certain ' rent, we may take the remunerative or risk rate at 8 per cent., and for the remaining period of 80 years duration, at 10 per cent. That is to say, the 8 per cent. will rule over the period of 15 + 5 = 20 years, and the 10 per cent. over the period 20 + 80 years = 100 years.

ANNUITIES TO BE VALUED.

£500	per annum for	1 year	deferred	15 years	at 8 per cent.
£650	" " "	1 "	"	16 "	
£750	" " "	1 "	"	17 "	
£900	" " "	1 "	"	18 "	
£1,500	" " "	1 "	"	19 "	
£2,500	" " "	1 "	"	20 "	at 10 per cent.
£3,666	" " "	79 years	"	21 "	

Valuation by the formula 5.

$$\frac{\left\{\begin{array}{l}(500 \times 1 \times 11{\cdot}976) + (650 \times 1 \times 11{\cdot}627) + (750 \times 1 \times 11{\cdot}288) + (900 \times 1 \times 1095) + \\ (1500 \times 1 \times 10{\cdot}96) + (1500 \times 1 \times 10{\cdot}640) + (2500 \times 1 \times 10{\cdot}330) + (3666 \times 0 \times 311{\cdot}03)\end{array}\right\}}{1.333 + \frac{26{\cdot}87 \times 8}{100} \times 10{\cdot}64 + \frac{321{\cdot}36 \times 10 \times 1}{100}}$$

$$= \frac{1213896153}{55{\cdot}502} = £21{,}871$$

Deducting for—

Mineral rights duty .	. 3·75 per cent.	
Royalty welfare levy	. 3·75 ,, ,,	
Management costs .	. 5·00 ,, ,,	
	12·50 ,,	2,734
Net valuation		£19,137

If the annuities valued as above had been those derivable by way of estimated profits from the working of a colliery instead of by way of rental, the process followed in the valuation would have been the same except that the risk rates one would have taken would have been higher, being determined according to the extent of the risk attending the exploitation of the mineral deposit and the disposal of the product mined. In all cases, however, the amount of the accumulative or 'gilt edged' interest would be the same. In the example above this is taken at 3 per cent.

In the valuation of the colliery as a current going concern, inasmuch as such plant and machinery, as would be the property of the lessee and not the lessor (in present circumstances the lessor of all coal mines in the United Kingdom is the State), would not be disposable until the termination of the lease, the present value would be a lump sum representing the existing value of the same, discounted at say 5 per cent. per annum, for the unexpired term of the lease. Consumable stocks (*e.g.* timber, oil, grease, canvas, etc.), are covered by the working cost and would not be subject to valuation.

Mr. Naish in his valuable treatise recites certain cases requiring special treatment, for the manner of the elucidation of which the reader is referred to the work in question, but the formulae which have been reproduced above meet the majority of the cases with which the valuer of mineral properties will have to deal.

SECTION XL

EXPLOSIVES

Contributed by Arthur Marshall, A.C.G.I., F.I.C., etc., author of 'Explosives, their History, Manufacture, Properties and Tests,' 3 vols., 'A Short Account of Explosives,' 'A Dictionary of Explosives')

(Pp. 949–953)

SECTION XL

EXPLOSIVES

(Contributed by Arthur Marshall, A.C.G.I., F.I.C., etc., author of 'Explosives, their History, Manufacture, Properties and Tests,' 3 vols., 'A Short Account of Explosives,' 'A Dictionary of Explosives.')

Blasting Explosives.

These are the explosives with which the engineer is most concerned. There are a number of varieties available, and they differ from one another in physical properties, in power and in violence. As regards physical properties some are powders, more or less coarse, like gunpowder, and some are plastic, like blasting gelatine, but many are intermediate between these. Sometimes they are made into hard cylindrical pellets, but more often they are in the form of cartridges wrapped in paper. Many of them contain hygroscopic salts, such as ammonium nitrate or sodium nitrate, and for these the paper is made damp-proof.

The power of an explosive may be measured by firing a cartridge of known weight in a lead block and measuring the enlargement of the bore-hole (Trauzl test). Another method is to fire a charge of the explosive out of a gun at a ballistic pendulum, suspended immediately in front of the muzzle and measuring the swing imparted to the pendulum. These tests must, of course, be carried out under standard conditions if the results are to be comparable with those obtained by other experimenters.

The violence of an explosive depends upon the rate at which it detonates. A column of explosive when detonated at one end develops a wave of detonation which travels with a velocity of some thousands of metres per second. This varies somewhat with the diameter of the column and the degree of confinement and other conditions, but is a fairly definite quality. It increases as a rule with the density of the explosive, but some explosives, if compressed too much, become difficult to explode, and so there may be only partial explosion or a total missfire. The properties of a few typical explosives are given at the end of this Section.

Power is always a desirable quality in an explosive, for the more powerful it is the less is one obliged to use. The violence, however, should be appropriate to the use to which the explosive is to be put. If the velocity of detonation be very high the explosive has a shattering effect, therefore when it is desired not to break up the rock or other material too much, it is advisable to use a comparatively mild explosive.

Black Powder.

Black powder or gunpowder is a mixture of saltpetre, charcoal and sulphur, in about the proportions 75 : 15 : 10. It is much less violent than the more modern blasting explosives. Considerable quantities are still used, especially in quarries and open workings, but the amount is falling. It has less power than modern explosives and is also objectionable because it generates a large amount of smoke and poisonous fumes. With gunpowder, even more than with high explosives, it is essential that the charge be well confined by tamping the bore-hole with clay or sand, otherwise it will produce little effect. It is best applied in 'sprung' bore-holes, that is to say the bottom of the hole is enlarged into a chamber by firing one or more small preliminary charges before the final charge of gunpowder is inserted. Black powder may be used advantageously in obtaining block stone and monumental stone, also in blasting limestone for kilning, because high explosives develop shatter cracks in it with the result that the kiln becomes choked with powder.

Black powder made with sodium nitrate (Chile saltpetre) instead of potassium nitrate is cheaper and more powerful, but is even slower and takes up moisture from the air more. It should not be used in rock that is much fissured.

Dynamites.

Until the latter part of the nineteenth century gunpowder was practically the only explosive manufactured or used for all purposes; as a propellant in firearms, for blasting and as a filling for shell. Then Alfred Nobel succeeded in making comparatively safe explosives, consisting

largely of nitroglycerine. These are generally called dynamites, but the jelly-like material made by mixing the liquid nitroglycerine with about 8 per cent. of collodion cotton (a variety of nitro-cellulose) is known as blasting gelatine. Gelignite, which is a variety of explosive much used in Great Britain, consists of 50 to 63 per cent. of nitroglycerine, thickened with collodion cotton and mixed with potassium or sodium nitrate and wood meal. Gelatine dynamite is a similar mixture but richer in nitroglycerine, of which it contains 70 to 77 per cent. Ammon-Gelignite contains a comparatively small proportion of nitroglycerine, but also has some ammonium nitrate. In Great Britain the term dynamite is generally applied to a mixture of about 75 per cent. of nitroglycerine absorbed in 25 per cent. of kieselguhr. Although this is not so powerful as the gelatinised explosives that have just been mentioned, it has the advantage that it develops its full violence when only slightly confined.

In the United States a range of dynamites is made containing different proportions of nitroglycerine from 5 or 10 per cent. upwards. The *straight dynamites* contain also wood pulp and sodium nitrate together with small quantities of other substances. For the weaker grades some of the wood pulp is often replaced partly by flour and sulphur. In the *gelatin dynamites* the nitroglycerine is gelatinised by the addition of a little collodion cotton. This prevents the liquid nitroglycerine exuding and consequently renders the explosives safer, especially in damp places. The *ammonia dynamites* contain a considerable proportion of ammonium nitrate. *Ammonia gelatins* contain ammonium nitrate and gelatinised nitroglycerine. The 'grade' of a straight dynamite represents the percentage of nitroglycerine that it contains; in the other varieties the grade is supposed to give the strength in terms of straight dynamite. Thus 40 per cent. straight dynamite contains about 40 per cent. of nitrogylcerine, and 40 per cent. gelatin dynamite or 40 per cent. ammonia dynamite is supposed to be of the same power, but actually is generally rather weaker.

Low Freezing Nitroglycerine.

A grave objection to explosives containing ordinary nitroglycerine is that the substance is liable to freeze to a crystalline solid which has a melting point of 13° C. (55° F.). When frozen they are less sensitive to detonation but more so to blows; in the semi-frozen state they are still more sensitive to blows and consequently very dangerous. In this condition they have caused many accidents. Frozen cartridges should be thawed before use by placing them in a special thaw-pan with a water jacket containing warm water. They should not be thawed by placing them near a fire; this may appear obvious, but many fatal accidents have been caused in this way.

By the addition of various substances to nitroglycerine the freezing point can be reduced so much that it will no longer become really hard even under severe winter conditions. In America nitrotoluene was at one time used extensively for this purpose, and in Germany nitrochlorohydrin, but now the tendency is to use dinitro-glycol. This is a substance very much like nitroglycerine and an equally powerful explosive, and it can be manufactured at a comparable price. All the nitroglycerine explosives made now in the United Kingdom are low-freezing, and a prefix, such as 'Polar' or 'Antifrost,' is added to the name to show the fact, as 'Polar Ammon Gelignite.' Fatal accidents due to freezing have consequently ceased.

Ammonium Nitrate Explosives.

Explosives of which the main constituent is ammonium nitrate are used more and more and they are comparatively safe to handle. Ammonium nitrate alone can be detonated under extreme conditions, as was shown by the appalling disaster at Oppau in Germany in 1921, but to secure an explosive that will not give rise to the danger of missfires it is necessary to add not only a proportion of combustible matter to combine with the excess of oxygen in the nitrate, but also a small quantity of some fairly sensitive explosive such as nitroglycerine or trinitrotoluene.

Coal Mine Explosives.

In all the principal countries that possess coal mines there are stringent regulations as to the explosives that may be used in them. The object of course is to prevent the use of those that have too much tendency to ignite mixtures of fire-damp and air or coal-dust and air. In England these explosives are tested in a special testing gallery at Buxton, where they are fired from a steel cannon into a large cylinder containing a mixture of methane and air, and also into a mixture of coal-dust and air. The most severe conditions that may occur in a coal mine are thus imitated. If no ignitions occur the explosive is placed on the 'Permitted List,' and it is called a 'Permitted Explosive.' There are similar testing stations in the United States, Germany, France and Belgium. In the United States the testing station is conducted by the Bureau of Mines under the Federal Government. As the regulation of the mines comes under the individual states the Bureau has no direct power and can only make recommendations, and the approved mixtures are consequently called 'Permissible Explosives.'

Nearly all the special explosives used in coal mines contain a considerable proportion of ammonium nitrate, which gives a comparatively cool flame with little tendency to cause ignitions. This tendency is further reduced by the addition of some 10 or 25 per cent. of a 'cooling agents,' such as sodium chloride or ammonium chloride or oxalate. This, of course, also diminishes the strength of the explosive.

Up to the end of 1931 there was a sort of modified gunpowder called 'Bobbinite' on the Permitted List, but this has now been discontinued. As it had only a low rate of explosion it gave a greater proportion of large coal. It was, however, considered to have a slightly greater tendency to ignite fire-damp than the other permitted explosives, and so, after a controversy lasting many years, it has been removed from the list. Millions of pounds of gunpowder are still used in coal mines, but only in comparatively safe localities.

Sheathed Cartridges.

The safety is increased considerably by enclosing each cartridge in a sheath containing some substance which tends to extinguish the flame. Various materials have been found effective, but as the result of investigations by the Safety in Mines Research Board a layer ⅛ in. thick of sodium bicarbonate round each cartridge is specially recommended, and such sheathed cartridges are being used extensively in Great Britain. It is found that the sheath causes no loss of power; it has a cushioning effect on the explosion and therefore increases the proportion of lump coal.

Low Density Explosives.

The proportion of lump coal is also increased by using explosives of very low density containing a bulky saw-dust or plant fibre instead of wood meal. The bulk density can thus be reduced as low as 0·7.

Chlorate Explosives.

There are some blasting explosives which contain neither nitroglycerine nor ammonium nitrate, but mostly they are of minor importance commercially. Many attempts have been made to produce satisfactory explosives containing chlorate or perchlorate as the oxygen carrier, but they suffer under two serious disadvantages: they are rather expensive and are more sensitive than other commercial explosives to blows and friction. Cheddite, one of the most successful, contains chlorate and a nitro-compound together with 5 per cent. of castor oil, which reduces the sensitiveness. In Germany a mixture of 90 parts potassium chlorate and 10 parts mineral oil is used in the potash mines and is called Miedziankit or Choratit 3.

Liquid Oxygen Explosives.

A powerful explosive is obtained by absorbing liquid oxygen in a porous combustible material, such as lamp black or wood meal. It can be fired directly by means of safety fuse, but is more reliable if an electric detonator be used. The materials are cheap, but there are a number of disadvantages: the cartridge must be fired before too much of the liquid oxygen has evaporated, and the explosive is rather sensitive. Consequently its use requires a higher degree of skill on the part of the shot-firer, and of course there must be a supply of liquid oxygen at hand. On the other hand, missfires are not dangerous because the oxygen all evaporates off, leaving only inert matter. On the Continent this explosive is used on a fairly large scale, especially in iron ore mines of Lorraine; in Great Britain, although attempts have been made to introduce it, the consumption has fallen heavily since 1929. They are really only suitable for use in porous rocks which allow the oxygen to escape as it evaporates.

Cardox.

Liquid carbon dioxide has also come into use for blasting purposes, especially for coal. The 'Cardox' cartridge consists of a hollow steel cylinder, 2 or 3 inches in diameter, containing a few pounds of liquid carbon dioxide and a heater composed of a mild but hot explosive, which can be fired electrically. When this is done the heater converts the liquid into gas, the pressure shears a steel closing disc in the end of the cylinder, the gas escapes and breaks down the coal. The cylinder is, of course, placed in a bore-hole and firmly secured in position.

Hydrox.

This is a somewhat similar device, and is also not strictly speaking an explosive. A mixture of sodium nitrite and ammonium chloride in a container of steel tubing is inserted into the bore hole and is fired by a powder fuse, whereupon it decomposes with the evolution of gas. Like Cardox it is finding increasing favour for bringing down coal.

Procedure in Blasting.

As regards the drilling of the bore-hole, see Section XL. (p. 886, *et seq.*). The hole is cleaned out carefully and the cartridges of explosive are inserted one after the other and pressed home with a wooden tamping rod. Into the last cartridge, that nearest the mouth of the hole, is inserted the detonator. If an electric detonator be used the two wire leads are arranged to

emerge from the hole. If the detonator be an ordinary one it is before insertion provided with a piece of safety fuse of the required length. One end of this is pushed into the copper detonator shell which is crimped on to the fuse. *Safety fuse* is a cord of jute or other fabric suitably waterproofed and provided with a fine core of gunpowder, which burns at the rate of 2 feet a minute.

The free portion of the bore-hole is now filled with a tamping of clay or sand, or preferably a 3 : 1 mixture of sand and clay, pressed gently but firmly home, and the shot is then ready for firing when everyone has retired to a safe distance.

The leads from electric detonators are connected by means of a considerable length of insulated wire with a source of current, which may be either a main or a hand-operated machine called an 'exploder.' A number of shots can be fired simultaneously with electric detonators.

Simultaneous shots can also be fired by means of a *detonating fuse*, otherwise called 'Cordeau,' which consists of a core of a detonating explosive in a suitable envelope. The most usual variety is composed of trinitrotoluene in a lead tube, and has a velocity of detonation of about 5,000 metres per second. Flexible cordeau is also made by enclosing a core of penthrite or fulminate in a waterproofed textile cover.

Demolitions.

For blowing up buildings and machinery the procedure is much the same as for obtaining minerals out of the earth, but in some cases it is not feasible to bore a hole to take the explosive. It must then be attached to the outside, and the most violent explosives should be used, such as dynamite, as these lose less of their effect under these conditions. The charge should be placed in intimate contact with the object to be blasted, and should be covered over with a good layer of clay to confine it as far as possible.

Steel plates can be cut in this way with a string of cartridges of Arctic Dynamite, and a ship can be divided in two. The same explosive is used for increasing the flow from oil wells and artesian water wells; a considerable charge is enclosed in an iron container, lowered to the bottom of the well and there fired. To break up heavy castings a hole is bored and a chamber made at the bottom by firing a small charge without stemming and then the main charge is fired with stemming. For this purpose ammon gelignite may be used; it is also recommended for breaking up brickwork. For submarine work and for deepening rivers the gelatinised nitroglycerine explosives are used, as they are less affected if a small amount of water gets through the waterproofing. The harder the rock the more nitroglycerine the explosive should contain. The manufacturer of the explosives will give advice and help in carrying out any of these operations, or similar ones.

For military demolitions ordinary commercial explosives are sometimes used, but as they are rather dangerous under the strenuous conditions of active service, special ones are issued. In the British Army blocks of wet compressed guncotton are used, fired by a primer of dry guncotton, which in turn is set off by a detonator fired either electrically or by safety fuse.

Shell Fillings, etc.

Shells can only be charged with very insensitive explosives, otherwise they would explode in the bore of the gun when it is fired. The two substances that are most used are trinitrotoluene (trotyl or T.N.T.) and picric acid (lyddite). It is usually mixed with a considerable proportion of ammonium nitrate: Amatol 80/20 is a mixture of 80 parts ammonium nitrate and 20 of T.N.T., and similarly Amatol 40/60 consists of 40 per cent. ammonium nitrate and 60 per cent. T.N.T. Picric acid is still used in the British Navy. It has the disadvantage that it forms dangerously sensitive picrates with lead, iron, and some other substances. Although it is insensitive enough to stand the shock of discharge, shells charged with it will not as a rule penetrate modern armour plate, but detonate before they have got through it.

Shrapnel shells are filled with bullets with a small charge of gunpowder to eject them before the shell reaches its objective.

A shell is caused to explode by means of a fuse fixed either into the nose or the base. There are two varieties: time and percussion fuses. Time fuses act at a determined time after the discharge of the gun, and are generally fitted to shrapnel shell; percussion fuses act when the shell strikes its object.

Grenades, aerial bombs, naval mines and torpedo warheads are filled with the same explosives as shells or similar ones.

Detonators.

Fulminate of mercury is no longer the only substance used for filling detonators, as lead azide has replaced it to a considerable extent. There are also composite detonators containing a main charge of T.N.T. or tetryl primed with fulminate or azide. In this country two sorts are made: a fulminate detonator loaded into a tube of drawn copper 6 mm. in diameter, and a tetryl-azide detonator in an aluminium tube. The latter may not be used in dangerous coal mines. Of the various sizes mentioned on p. 863, Nos. 6 and 7 are those generally used. In an electric detonator the electric fuse fits into the tube just above the explosive. Both high and low tension electric detonators are in general use, but the latter are preferable for multiple shot-firing.

Propellants.

Black powder is still used to a small extent in *shot-guns* on account of its cheapness and reliability. Its disadvantages are the smoke it gives off, the serious fouling of the barrel and the heavy recoil. The smokeless shot-gun powders consist essentially of nitrocellulose partially or entirely gelatinised by the use of a solvent, such as ether-alcohol, which is afterwards dried out. By suitable manipulation the powder is made into porous grains which are so bulky that a charge occupied about the same space in the cartridge case as the much greater weight of black powder which gives the same muzzle velocity.

The 'powders' for use in *rifled fire-arms* are not porous. They are made in the form of flakes, rods, cords, tubes or strips. The longer the barrel, the greater the time that the powder has to burn before the projectile leaves the muzzle, and consequently the thicker are the flakes, tubes, etc. There are two main classes of military powders: those consisting almost entirely of nitrocellulose, called 'nitrocellulose powders,' and those containing also a considerable proportion of nitroglycerine, called 'nitroglycerine powders.' The British service powder, cordite, is of the latter type. Most of the foreign powers use nitrocellulose powders, but the Germans have both.

Precautions.

Explosives are made to explode, and consequently should be treated with due respect. Every endeavour is made to prevent them from being unduly dangerous, but they can never be safe. Their use and storage is regulated by the rules drawn up by H.M. Chief Inspector of Explosives, which may be studied in the 'Guide to the Explosives Act,' published by the Stationery Office. An explosive must be stored in properly constructed magazines, for which a licence must be obtained. Detonators should not be kept in the same room with other explosives. Magazines must not be repaired until all the explosives have been removed. The transport of explosives is also subject to official regulations.

Explosives containing nitroglycerine and nitrocellulose are liable to deteriorate on keeping, especially in hot climates, and consequently should be inspected and tested from time to time.

When fired explosives almost always generate some carbon-monoxide gas, even though they contain sufficient oxygen for complete combustion. As this gas is poisonous underground workings should be well ventilated, and the site of an explosion should not be approached too soon.

Properties of Typical Explosives.

Explosive.	Density. (Water = 1.)	Power. c.c./10 g.	Velocity of Detonation. Metres/sec.
Blasting gelatine	1·55	520	5500
Gelatine dynamite	1·6	415	5000
Gelignite (60 per cent. nitroglycerine)	1·6	340	5000

SECTION XLI

RADIOCOMMUNICATION

(Pp. 957–973.)

(Compiled by G. Parr, M.I.E.E.)

SECTION XLI

RADIOCOMMUNICATION.

(Compiled by G. Parr, M.I.E.E.)

GENERAL.

The term Radiocommunication covers all methods of transmitting intelligence from point to point by means of electromagnetic radiation through space, and thus includes not only broadcasting of speech and music but signalling from ships and aircraft, transmission of identification or warning signals from beacons, direction-finding signals, and television. Receivers intended for long distance reception of Morse signals or speech are referred to as 'communication receivers' in distinction to the 'broadcast receivers' used for listening to programmes regularly transmitted by the broadcasting stations of the world.

The regulations under which radiocommunication is carried out are drawn up by an International Radio Convention but international broadcasting policy, such as the allocation of wavelengths, power of stations, and interference problems is determined by an International Broadcasting Union.

The wavelength bands at present allocated for broadcasting purposes are approximately :—

1,000–2,000 m.	300–150 kc/s	Long waves
800–200 m.	1,500–375 kc/s	Medium waves
50–13 m.	6–2·3 Mc/s	Short waves

Other wavebands have been allocated as follows :—

Broadcasting : 13, 16, 19, 24, 31, 41, 49 m.

Amateur radio : 144–145 Mc/s ; 1215–1300 Mc/s ;
5,650–5,850 Mc/s ; 10,000–10,500 Mc/s.

The definition of radiation in terms of its wavelength is being gradually displaced by the use of the frequency to denote the classification, and the term 'short-wave' is more accurately 'high-frequency.'

The classification of radio waves in terms of frequency is given by B.S.I. 204—1943, as :—

Very low frequency (audio frequency)	Below 30 kc/s
Low frequency	30–300 kc/s
Medium frequency	300–3,000 kc/s
High frequency	3,000–30,000 kc/s
Very high frequency	30,000–300,000 kc/s
Ultra-high frequency	300,000 kc/s–3,000 Mc/s
Super-frequency	3,000 Mc/s–30,000 Mc/s

The use of higher frequencies for radiocommunication has several advantages, chiefly in the greater transmitter efficiency obtainable and in the ability to direct the radiation within a narrow beam towards the desired reception point. A further advantage is that a greater number of stations, each having a frequency bandwidth of the full range of speech and music, can be accommodated within a given high frequency band without interference.

The disadvantages of the higher frequencies, particularly those corresponding to a wavelength below 10 m., are that the absorption along the earth's surface is considerable and unwanted reflection or refraction takes place. Communication on very high frequencies is usually limited to stations within horizon distance, although no definite rule can be established.

WAVELENGTH-FREQUENCY CONVERSION TABLE.

Formulæ: $\text{Wavelength in metres} = \frac{300,000}{\text{frequency in kc/s}}$.

$\text{Wavelength of oscillatory circuit} = 1,884\sqrt{LC}$

where L and C are in μH and μF respectively.

Frequency. kc/s.	Wavelength. m.	LC.	Frequency. kc/s.	Wavelength. m.	LC.
100	3,000	2·5330	550	545·45	0·0837
150	2,000	1·1258	600	500	0·0703
200	1,500	0·6332	650	461·54	0·0599
250	1,200	0·4054	700	428·57	0·0514
300	1,000	0·2814	750	400	0·0450
350	857·15	0·2067	800	375	0·0395
400	750	0·1583	850	352·94	0·0350
450	666·66	0·1250	900	333·33	0·0312
500	600	0·1013	1,000	300	0·0253

To extend this table for use with multiples or sub-multiples of the quantities, the following factors should be used:—

Range of Frequency.	Wavelength Factor.	LC Factor.
10–100 c/s	10,000	100,000,000
100–1,000 c/s	1,000	1,000,000
1–10 kc/s	100	10,000
10–100 kc/s	10	100
1–10 Mc/s	10^{-1}	10^{-2}
10–100 Mc/s	10^{-2}	10^{-4}
100–1,000 Mc/s	10^{-3}	10^{-6}

Example.—To find the wavelength corresponding to 15 Mc/s:

The wavelength in the table is given as 2,000 for 150 kc/s. For 15 Mc/s divide by 100, giving 20 m. as the wavelength. The LC product is 1·1258 × 100, or 112·58.

FREQUENCY MODULATION.

The usual method of transmitting speech or music in radiocommunication is by varying the amplitude of a radio frequency carrier wave, the amount of variation being proportional to the intensity of the sound. This method is termed *amplitude modulation.*

An alternative method, first suggested by Round in 1921 (1), and developed by Armstrong (2), is to maintain the amplitude of the carrier wave constant and vary its frequency in proportion to the frequency of the modulating signal. In this system, known as *frequency modulation*, two changes in the carrier wave take place: the frequency of the modulating signal is caused to vary the carrier at a corresponding frequency, and the amplitude of the modulating signal controls the frequency deviation of the carrier about a pre-determined value. For example, a 1,000 c/s note of low intensity will vary the carrier frequency of 1,000 kc/s from 1,000·1 to 999·9 at a rate of 1,000 c/s.

Four important advantages are given by frequency modulation over the more usual amplitude modulation: greater signal-to-noise ratio, lower transmitter power for a given output from the receiver, less distortion of the modulating voltage, and greater freedom from interference between adjacent stations. The disadvantages are that reception must be confined to ultra-short wave 'direct path' transmission if distortion of some of the frequency components and the distortion introduced by selective fading is to be avoided.

The improved signal-to-noise ratio, which is a feature of the system, is still further increased by the use of 'pre-emphasis'—the increase in amplification of the higher frequencies at the transmitter. This requires corresponding 'de-emphasis' to correct the tonal balance at the receiver.

The successive increases in signal-to-noise ratio given by various factors in the transmission can be tabled as follows:

Increase due to phase modulation . . .	2·9 times
„ due to wider modulation pass band .	25 „
„ by pre-emphasis and de-emphasis .	5·5 „
„ by more efficient transmission . .	2 „

giving an overall improvement of 800 times.

Phase-modulation.

In the method of transmission known as *phase-modulation* the amplitude of the carrier remains constant and its phase angle with regard to its unmodulated condition is varied in accordance with the frequency of the modulating signal. The magnitude of the phase change is determined by the intensity of the signal.

The mathematical expression for a frequency-modulated wave (assuming sinusoidal form) is

$$E \sin(2\pi f_c t - M \cos 2\pi f_m t)$$

where f_c is the carrier frequency, f_m the modulating frequency, and M is the ratio of frequency deviation to the modulating frequency, termed the Modulation Index.

For phase-modulation, the expression becomes:

$$E \sin(2\pi f_c t + \phi M \sin 2\pi f_m t)$$

the phase angle covered being ϕM, where ϕ is a constant and M is proportional to the amplitude of f_m.

Receivers for F.M.

A diagrammatic layout for a frequency-modulation receiver is shown in Fig. 1. The circuit differs from an amplitude-modulated receiver in the inclusion of a 'limiter' and frequency-amplitude conversion stages. The dipole aerial is connected to one or more radio frequency

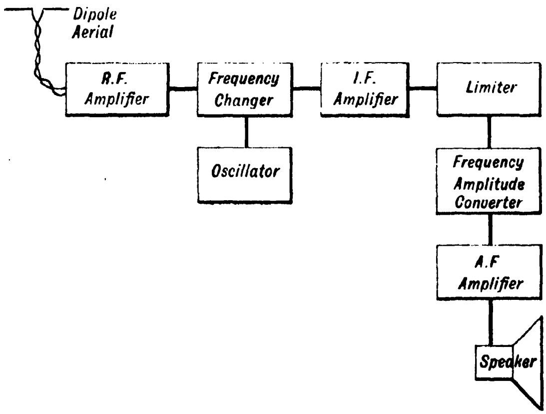

FIG. 1.—Schematic diagram of receiver for frequency-modulated signals.

amplifying stages, followed by a frequency changer, as in the conventional superheterodyne. The output from the intermediate frequency amplifiers is fed to the limiter, which has the function of reducing any amplitude modulation of the carrier due to noise, interference, or variation in the frequency response of the pass band. A common form of limiter is a saturated amplifier stage, whose amplification factor is inversely proportional to the amplitude of the input signal.

A common form of frequency-amplitude converter employs a frequency discriminator similar to that used for automatic frequency correction in superheterodyne receivers. This translates the I.F. carrier frequency into a D.C. bias voltage which is zero at the correct carrier setting and becomes increasingly positive or negative for frequencies above or below this value. A modulated

carrier wave applied to such a circuit will therefore give an output voltage which will vary with the A.C. component of the carrier wave. The audio frequency amplifier which follows the frequency converter is on conventional lines but is designed to take advantage of the wider audio frequency range of the transmitted signal.

Experimental Transmissions.

A large number of experimental frequency-modulated transmitters have been in operation in America for over three years, and the service is also being established as an adjunct to the ultra-short wave television transmissions. In this country an experimental station at Wrotham is under construction and will be operating in 1949. The wavelength is 3·3 metres and the power has been provisionally stated to be 25 kW.

BRITISH TELEVISION.

The present television service was inaugurated in 1937 and, according to official statement, will remain as standard for many years. The service area of the London station (Alexandra Palace) within which good reception can generally be relied on is bounded by a circle of approximately 25 m. radius, passing through Tring, Slough, Woking, Redhill, Sevenoaks, Tilbury, Pitsea, Waltham, and Hitchin. Freak reception has been reported from widely scattered areas, including Jersey, Isle of Wight, Bristol, the Midlands, and the Continent.

Details of the System.

The vision signal is transmitted on a frequency of 45 Mc/s and the accompanying sound on a frequency of 41·5 Mc/s. The band width of the vision transmitter is 3 Mc/s, and the frequency response of the sound transmitter is flat from 30 to 10,000 c/s. The radiation is vertically polarised. The peak output of the vision transmitter (' full white '—see on) is 17 kW, and that of the sound transmitter 12 kW.

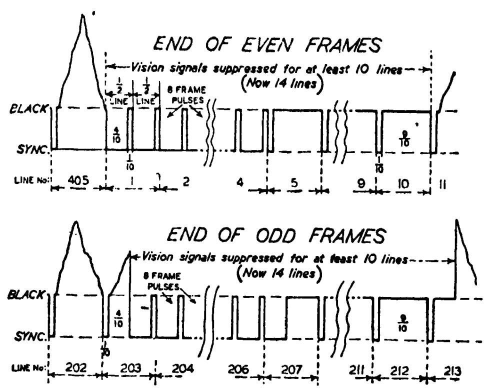

FIG. 2.—Waveform of vision signal from the London station, showing difference between odd and even frames.

A characteristic of the British system is that a ' positive ' signal is radiated, *i.e.* the amplitude of the carrier wave is proportional to the picture brightness at any instant, and maximum carrier corresponds to full white tone in the picture.

In order to provide for a synchronising signal which can be readily separated from the vision signal, the level of the carrier wave corresponding to black in the picture is set at 30 per cent. of maximum amplitude. At the end of each line signal transmitted the carrier amplitude falls below this datum (see Fig. 2), giving a synchronising pulse which can be readily separated from the vision

signal by a form of amplitude filter circuit in the receiver. Such a pulse also serves to 'black out' the beam of the cathode ray tube so that its return path on the screen at the end of each line and frame is not visible.

Interlacing.

The picture is scanned with 405 lines, 25 times per second. In order to minimise flicker a repetition rate of 50 per second is desirable, and this can be achieved in effect without increase in the band width of the signal by the system known as interlacing.* The picture is scanned with half the total number of lines ($202\frac{1}{2}$) in $\frac{1}{50}$th sec. to form one 'frame,' a gap being left between each line equal to the thickness of a line. At the completion of this scan the spot returns to the beginning of its travel and traces a second set of $202\frac{1}{2}$ lines in the spaces left between the first set. The eye thus receives an impression of a complete picture repeated 50 times per second, as it does not appreciate the interval between the scanning of adjacent lines.

The diagram of Fig. 2 shows the waveform of the vision signal at the end of the even and odd frames, the displacement of the spot by half a line being accomplished by a variation in the synchronising impulses.

Programmes.

Programmes are transmitted every day from 3 to 4 P.M. and 8.30 to 10.0 P.M. A test film is also transmitted each morning from 11 A.M. to noon for the setting-up and demonstration of receivers.

The programmes include variety, concerts, full-length plays from the studio and outside theatres, illustrated talks and interviews, and films adapted for television. The B.B.C. has its own newsreel unit.

Outside events are covered by two mobile transmitting units which can cover distances up to 30 m. from Alexandra Palace. In addition, a special cable has been laid in London with tapping points at suitable intervals to enable direct transmission of events of national importance from the mobile unit to the transmitting station.

Miscellaneous Data.

The staff of the television station numbers about 300 on the programme side and 200 engineers and technicians. The Head of the Television Service is Norman Collins, and the Programme Director is Cecil McGivern. D. C. Birkinshaw, M.B.E., is the Superintendent Engineer, and the Studio Engineer-in-Charge is H. Baker.

The total number of television licences held at the end of 1948 was approximately 75,000, the cost of a combined radio reception and television licence being £2. The production of television receivers amounted to a monthly rate of 6,430 in 1948, compared with 2,300 in 1947. It is expected that a total of 200,000 receivers will be issued by the end of 1949.

Extension of Service.

By the end of 1949 it is expected that a television station will be in operation at Sutton Coldfield, Birmingham, to serve the Midlands area. This station will be connected to the London television station by means of a series of relay links at Harrow Weald, Dunstable, Blackdown Hill, and Rowley Regis, through which the programmes will be transmitted on ultra-short waves, and also by coaxial cable.

The transmitter at Sutton Coldfield will operate on a frequency of 61·75 Mc/s for vision and 58·25 Mc/s for sound. The power of the vision transmitter will be 35 kW., which should provide adequate signal strength over a radius of 50 m. from the transmitter.

It will also be possible to transmit programmes in both directions, and the relative merits of the ultra-short wave link and the cable will be studied to determine the most economical method of relaying programmes to other parts of the country. The mast at Sutton Coldfield will be 800 ft. in height, which is the maximum so far attained by the B.B.C. service.

RADIO VALVES.

Base Connexions.

Since the war the use of radio valves fitted with an 'octal' base has become almost universal, and indirectly-heated valves operating from 4 volt A.C. are being replaced by 6·3 volt valves.

* Ballard, Brit. Pat. 420391 (R.C.A.).

The octal based valves originated in America and bear American type numbers, but equivalents are obtainable from the majority of British manufacturers.

A similar base to the octal base is fitted to Mazda valves, but the dimensions and the connexions to the pins differ. The points of difference are shown in Fig. 3 and in Table below. Care should be taken not to force an American octal base into a Mazda octal socket. The table gives the convention for the pin connexions in each type of base.

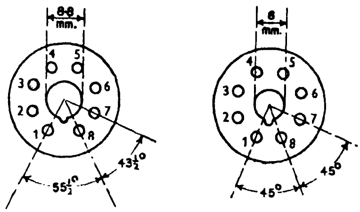

FIG. 3.—Illustrating the principal points of difference between the Mazda Octal-type base (left) and the American Octal Base. Note the spacing of the pins.

CONNEXIONS TO PINS OF VALVE BASES.

Pin No.	American Octal Base.	Mazda Type Octal Base.
1	In metal valves connected to the shell, in glass bulb valves, usually blank, or to internal shielding	Always filament or heater.
2	Always heater or filament . .	Cathode of indirectly heated (I.H.) valves, except in some diodes.
3	Varies, but usually anode . .	Anode or diode anode except in ½-wave A.C./D.C. rectifier when it is the cathode.
4	Varies	Varies. Always screen in pentodes.
5	Varies	Varies.
6	Usually a grid when present. Often omitted	Usually metallising, but a control grid in double triodes and pentodes.
7	Always heater or filament . .	Varies.
8	Usually cathode	Always heater or filament.
Top cap	Usually control grid . . .	Always control grid, but G_4 in octodes.

Pins are numbered clockwise with No. 1 to the left of the key when the base is held towards the viewer, key downwards.

In multi-grid valves, the grids are designated G_1, G_2, G_3, etc., in order outwards from the cathode.

Miniature Valves.

Developed during the war for use in portable and lightweight apparatus, miniature valves with all-glass bases are now fitted to many types of receivers. Typical dimensions of an all-glass based valve are 2 ins. overall length and ¾ in. diameter. The British type reference numbers are B.7.G and B.8.A., indicating the type of base used.

The pins in the base are of small diameter and comparatively fragile in comparison with the more robust split pin in the moulded base, and special precautions must be taken in fitting the valves into their sockets. Valveholders should be fitted with ' floating ' contacts to avoid bending the pins on insertion, and it is desirable to use a form of jig inserted into the socket when soldering the connecting wires in place.

Code of Practice.

The British Radio Valve Manufacturers' Association* have issued a booklet giving guidance to the designers of equipment employing electronic valves so that optimum performance and life may be secured. Some of the more important points are summarised below :—

1. The heater voltage should not vary more than 7 per cent. from the rated value. In certain rectifiers this permissible variation is much less.

2. Heaters of mains-operated valves should not be connected in series unless specifically designed for the purpose.

3. Valves should normally be operated base downwards, but if mounted horizontally, the plane of the filament should be vertical.

4. Mercury vapour rectifiers should never be operated in any other position than the vertical.

5. The potential difference between heater and cathode should not exceed 150 volt, except where specified as permissible.

6. The published ratings should be closely observed. The first maximum rating reached should be the limiting factor in the performance.

7. The layout should give adequate ventilation to ensure safe bulb temperature. This particularly applies to 'miniature' valves and valves in screening cans.

8. Valves should never be operated without a D.C. connexion between each electrode and the cathode. The resistance between grid and cathode may be $3 \cdot 5$ megohms in small valves with self-bias, but 1 megohm is recommended. The resistance for power valves (10 W dissipation should not exceed $0 \cdot 5$ megohm.

9. Valves should not be operated with the cathode current cut off for long periods, when the heater is still connected to the supply.

Microphony.

Microphony in a valve is the sound produced by small rhythmic variations in the output, caused by variations in the electrode spacing when mechanical vibrations reach them from an external source.

The effects of microphony can be minimised by the following precautions :—

1. The loudspeaker should be insulated from the chassis by rubber bushes, and should not be too close to the valves in the early stages of the receiver.

2. The chassis should be mounted on rubber bushes and not fixed rigidly to the cabinet.

3. Valves which are followed by the highest degree of amplification should be mounted in resilient holders with short flexible connexions to the socket contacts.

4. Valves can be shielded from direct impact of sound waves from the loudspeaker by interposing other components.

Mercury Vapour Rectifiers.

These need special care in mounting and putting into commission. If the rectifier has been stored or shaken in transit, the mercury should be volatilised from the cathode surface by running the cathode at operating temperature for at least 15 minutes before applying the H.T. voltage. The filament and anode should never be switched on simultaneously except in very small rectifiers on low loads.

The filament end of the rectifier should be kept as cool as possible, and power rectifiers should have a forced draught cooling if adequate ventilation is not practicable.

Flashover is frequently caused by excessive temperature, and a safety fuse should be inserted in the anode lead as a precaution.

FIXED RESISTORS.

Colour Code.

The values of resistance are marked on fixed resistors by means of a colour code, based on the colours of the spectrum and including black, brown, and white. The colours are applied in one

* 16 Jermyn Street, London, S.W. 1.

of the three ways shown in Fig. 4. In addition a fourth colour denoting the tolerance is sometimes added. If no fourth colour is present, the tolerance is 20 per cent.

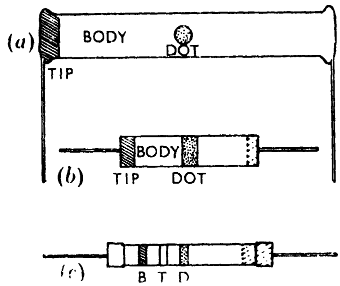

FIG. 4.—Three types of resistor, showing markings.

TABLE OF COLOUR CODE.

Body. (1st Significant figure).	Tip. (2nd Significant figure).	Colour.	Dot. (Number of zeros to follow).
0	0	Black*	0·0
1	1	Brown	0
2	2	Red	00
3	3	Orange	000
4	4	Yellow	0000
5	5	Green	00000
6	6	Blue	000000
7	7	Violet	
8	8	Grey	
9	9	White	

A convenient method of memorising the code is to associate the 'dot' colour with the following:—

Black	Tens	Yellow	Hundred thousands
Brown	Hundreds	Green	Megohms
Red	Thousands	Blue	Tens of megohms
Orange	Ten thousands		

The 'body' and 'tip' colours are then read in that order, mentally inserting a decimal point between the figures. Example:

Green—black . . . . . . 5 · 0
Brown—red . . . . . . 1 · 2

and the value of the dot is then read according to the above table.

Example: Green body, black tip, orange dot:
5 · 0 ten thousands.
or 50,000 ohms.

Note: Red body, green tip, green dot is read as
2 · 5 megohms.
or 2½ megohms, and not 25 megohms.

* Values below 10Ω are indicated by two black dots.

Preferred Values.

To simplify the stocks of resistors and the values specified in design practice, the Radio Component Manufacturers' Federation* has agreed on a series of preferred values of resistance which should be used in normal circumstances for radio receivers and electronic apparatus. Special values can still be supplied to requirements, but their use is deprecated. The table of preferred values is governed by the tolerance required, and the columns in the Table conform to the specified tolerances of 5 per cent., 10 per cent., and 20 per cent.

PREFERRED VALUES OF RESISTORS.

Tolerance.			Tolerance.			Tolerance.		
± 20 %	± 10 %	± 5 %	± 20 %	± 10 %	± 5 %	± 20 %	± 10 %	± 5 %

		130			4,300			
150	150	150	4,700	4,700	4,700	Higher values are in the same proportion.		
		160			5,100			
	180	180		5,600	5,600			
		200			6,200			
220	220	220	6,800	6,800	6,800			
		240			7,500			
	270	270		8,200	8,200			
		300			9,100			

FIXED CAPACITORS.†

Colour Code.

The colour code for fixed capacitors is based on the same series of colours as in the resistor code. Fig. 5 shows the arrangement of colours in two types of capacitor. In addition to the value markings there are colours for a complete range of tolerances from 1–10 per cent. and for D.C. voltage ratings. If only three colours are shown, it is assumed that the tolerance is 20 per cent. and the D.C. voltage rating is 500 volts.

* 22 Surrey Street, Strand, W.C. 2.

† It is now recommended that the term 'capacitor' be used in place of the original term condenser.'

The values are expressed in micromicrofarads (picofarads). A third significant figure is sometimes found in American practice, two of the colours being on one side of the capacitor and two on the other.

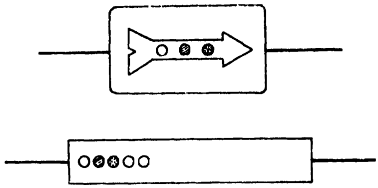

FIG. 5.—Two types of fixed capacitor, showing arrangement of colour dots.

BRITISH COLOUR CODE FOR FIXED CAPACITORS.

Colour.	Significance of First Three Colours.	Fourth Colour (Tolerance Per Cent.)	Fifth Colour (Voltage Rating).
Black	0		
Brown	1	1	100
Red	2	2	200
Orange	3	3	300
Yellow	4	4	400
Green	5	5	500
Blue	6	6	600
Violet	7	7	700
Grey	8	8	800
White	9	10	1,000

Note.—The American code is similar to the above, but has white 900 volt rating, gold 1,000 volt, copper 1,600 volt, and silver 2,000 volt.

Leakage.

A common cause of trouble in amplifier circuits is the use of capacitors which have a leakage current in excess of normal. It should also be appreciated that capacitors do not have an indefinite life in storage, and the use of old capacitors is a false economy owing to the risk of breakdown and faulty insulation.

The following table is based on the British Standard-Fixed Capacitors (B.S. 1082—1942). Group 1 includes all capacitors which are connected in a circuit in such a way that there is a risk

INSULATION RESISTANCE OF FIXED CAPACITIES (BRITISH).

Group.	D.C. Test Voltage.	Time of Application Min.	Rated Capacity μF.	Min. Insulation between	
				Terminals. $M\Omega \times \mu F$.	Capacitor and case $M\Omega$.
(1)	500	1	>1 ≯1	1,000 1,000	100 300
(2) Other than electrolytic	300	1	>1 ≯1	300 300*	30 100
Electrolytic with D.C. rated voltage	Rated voltage	3	All	7	100
Electrolytic with D.C. rated voltage (wet type)	Rated voltage	3	All	3	100

* Megohms only.

of shock if the capacitor develops a fault. Group 2 includes other capacitors to which no risk of shock is attached in event of failure.

The classification is for test purposes, and does not indicate the use to which the capacitor should be put.

Electrolytic Capacitors.

Electrolytic capacitors are frequently assembled in blocks in a common outer cover, the connecting leads being brought out at the ends. The values of capacity are also marked on the case in plain figures, but the connecting leads are colour coded to distinguish them. The arrangement of the internal connexions is identified as follows :—

+ A common positive connexion.	± Series connexion.
− A common negative connexion.	& Independent sections.

The spectrum order is also applied to the coloured leads, which then denote the capacities in descending order of magnitude :—

Positive connexions : red, yellow, green, blue, violet.

Negative connexions : black, brown, grey.

The centre tap of a voltage doubler capacitor is coloured white.

Examples.—(1) Two independent capacitors of $4\mu F$ and $2\mu F$ would be marked '4 & 2' and their leads would be coloured red and black for the $4\mu F$ section and yellow and brown for the $2\mu F$ section.

(2) Three capacitors of 8 ; 8 and $4\mu F$ with a common negative lead would have their leads coloured red, red, yellow and black.

Mains Transformers.

A number of transformers supplied for use in power rectifier units have coloured wires to indicate the windings to which they refer. The conventional code is shown in the drawing below.

Heater windings are usually of 18 or 16 s.w.g., while the rectifier heater winding may be 20 s.w.g. Some high tension transformers for use in cathode-ray tube equipment and those for use with half-wave or metal rectifiers have their secondary leads coloured red and red-and-yellow.

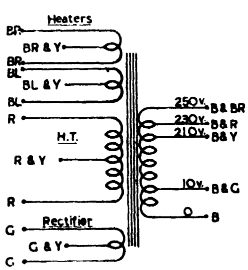

FIG. 6.—Colour code for transformer leads. BR = brown, BL = blue, B = black, Y = yellow, R = red, G = Green. Where two colours are indicated they are interwoven in the insulating sleeving.

If there is an electrostatic screen between primary and secondary windings it may be permanently connected to the core inside the transformer cover, or may be brought out to a flexible bare copper lead.

American power transformers are similarly colour coded but there may be variations in the rectifier filament winding (yellow and yellow-and-blue instead of green and green-and-yellow) and in the heater winding, which may be green and green-and-yellow. A voltmeter should always be used in doubtful cases in addition to checking the wire size.

In some American receivers the intermediate frequency transformers have their leads coloured according to the following code :—

H.T. wire . . .	Red	Grid wire . .	Green
Anode wire . . .	Blue	Earth wire . .	Black

This code can also apply to audio frequency transformers.

BRITISH COLOUR CODE FOR CARTRIDGE FUSES.

Colour.	Fusing Current.	Colour.	Fusing Current.
Black	60 mA.	Dark Blue	1·0 A.
Grey	100 mA.	Light blue	1·5 A.
Red	150 mA.	Violet	2·0 A.
Brown	250 mA.	White	3·0 A.
Yellow	500 mA.	Black and white	5·0 A.
Green	750 mA.		

BRITISH COLOUR CODE FOR WANDER PLUGS.

Red	H.T. + max.	Black	Common negative
Yellow	H.T. + 2	Brown	G.B. – max.
Green	H.T. + 3	Grey	G.B. – 2
Blue	H.T. + 4	White	G.B. – 3
Pink	L.T. +		

Note.—H.T. + 2 denotes second highest possible value, and so on.

MISCELLANEOUS DATA.

Attenuators.

An attenuator is a network of resistances or impedances designed to produce a known reduction in amplitude of a signal applied to its input terminals. For accurate working the impedance of the input source Z_1 and the impedance of the output load Z_2 should be matched. Attenuator networks are generally of three types: T-section, π-section, and bridged-T section (see Fig. 7).

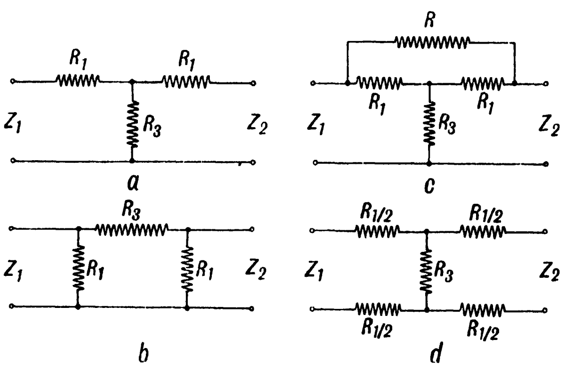

FIG. 7.—Types of attenuator circuit. (*a*) T-section, (*b*) π-section, and (*c*) bridged T-section. (*d*) is a balanced T-section to which the table refers.

The following table gives the attenuation in *db* for a symmetrical T attenuator for $Z_1 = Z_2 = 500$ ohms (Fig. 7*d*).

db.	R_1	R_2
1·0	28·8	4,330
2·0	57·3	2,152
3·0	85·5	1,419
5·0	140·1	822
10·0	259·7	351·4
20·0	409·1	101·0
30·0	469·3	31·65
40·0	490·1	10·00
50·0	496·8	3·162
60·0	499·0	1·000

Tone Control.

The majority of audio-frequency amplifiers require to be fitted with a form of tone control, either to suit the taste of the individual listener or, in the reproduction of gramophone records, to compensate for the deficiencies in the recording characteristic.

A variety of tone control circuits have been designed, based on the properties of resistance-capacitance or resistance-inductance combinations, and two basic forms are shown in Fig. 8.

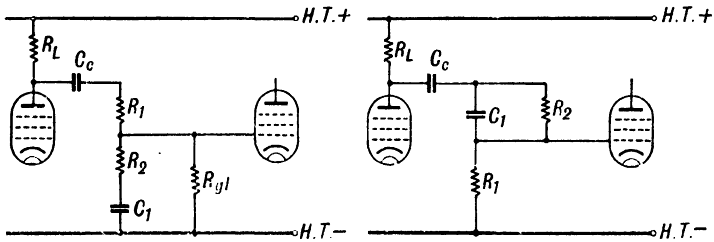

FIG. 8.

Details of Frequency Response.	*Component Values.*	*Details of Frequency Response.*	*Component Values.*
Bass lift, beginning at 300 c/s, rising 12 db at 50 c/s	R_L = 50,000Ω C_c = 0·01μF R_1 = 250,000Ω R_2 = 50,000Ω C_1 = 0·015μF Rgl = 1MΩ	Bass cut, beginning at 300 c/s, falling 11 db at 50 c/s	R_L = 50,000Ω C_c omitted C_1 = 0·001μF R_2 omitted R_1 = 1MΩ
Top cut, beginning at 2,000 c/s, falling 12 db at 10,000 c/s	R_L 50,000Ω C_c = 0·01μF R_1 = 250,000Ω R_2 omitted C_1 = 0·002μF Rgl = 1MΩ	Top lift, beginning at 2,000 c/s, rising 12 db at 10,000 c/s	R_L = 50,000Ω C_c = 0·02μF C_1 = 100μμF R_2 = 0·5MΩ R_1 = 0·1MΩ

Inductance.

Formulæ for the inductance of single layer coils are only strictly accurate for D.C. or low frequency A.C., as no method of allowing for uneven current distribution of current at high frequencies is available. The most widely used formula for single layer coils is that due to Professor Nagaoka :—

$L_s = 0{\cdot}00987\, D^2 n^2 l K$ microhenries.

where D = diameter of coil between wire centres (cm.)
n = turns per cm.
l = length of coil in cm. = $n \times$ total number of turns
L_s = inductance in μH. of a 'current sheet' inductance, *i.e.* a coil of infinitely thin tape with infinitely thin separation between turns
K = a factor depending on the ratio of D : l.

TABLE OF K FACTORS.

D/l.	K.	D/l.	K.
1·0	0·69	0·02	0·99
2·0	0·53	0·03	0·98
3·0	0·43	0·04	0·98
4·0	0·37	0·05	0·97
10·0	0·20	0·1	0·96

A closely wound coil with thin insulation approaches the ideal sufficiently accurately for the above formula to be used. If, however, the turns are spaced apart, a correction (due to Rosa) can be applied as follows :—

The reduction in inductance $\Delta L = 0{\cdot}006283\ Dnl(A + B)$. μH. where D, n, and l have the same significance and A and B are factors depending on the spacing and dimensions of the coil.

Rosa's Correction Factors.

$A = f(d/p)$ $B = f(D/l)$.

where d = wire diameter (cm.).
p = pitch in cm.

Ratio D/l	B.	Ratio d/p.	A.
0·02	0·11	0·1	− 1·55
0·03	0·17	0·15	− 1·35
0·04	0·2	0·2	− 1·05
0·05	0·22	0·25	− 0·83
0·1	0·27	0·3	− 0·65
0·5	0·32	0·35	− 0·5
1·0	0·33	0·4	− 0·36
2·0	0·33	0·5	− 0·14
3·0	0·33	0·6	+ 0·05
4·0	0·33	0·8	+ 0·34
10·0	0·34	1·0	+ 0·55

The value of ΔL calculated from this formula is then subtracted from the value found from Nagaoka's.

TABLE OF TURNS PER CM. LENGTH.

34	0·234	34	35	39
40	0·122	54	58	72

Effect of Screening Cans.

The effect of a screening can on the inductance can be calculated from the following table, which assumes that the top of the can is a distance equal to the diameter of the coil from the top

of the coil former. D_s is the diameter of the can and D the diameter of the coil. There is negligible difference between cans of square or circular cross-section.

REDUCTION IN INDUCTANCE DUE TO CANS.

Ratio of D_s : D.	Per Cent. Reduction.
10	0·13
8	0·25
6	0·6
5	1·0
3	4·5
2	15·0

Self-capacity of Short Solenoids.

Palermo gives :
$$C_s = \frac{\pi D}{3\cdot 6 \cosh^{-1}(p/d)}\ pF.$$
when l is not greater than D, and the symbols have the significance previously given.

Amplification.

The stage gain of a valve at audio frequencies is given by the following formulæ :—

1. At low frequencies $$G = \frac{G_m}{\sqrt{1 + \frac{1}{\omega^2 C^2 R_t}}}.$$

2. At medium frequencies $$G_m = \frac{\mu R}{R + R_a}.$$

3. At high frequencies $$G_h = \frac{G_m}{\sqrt{1 + \omega^2 C^2{}_1 r^2}}$$

where :

G_m = Gain at medium frequency.

R = Effective resistance of load resistor and grid leak in parallel ($R . R_g/(R + R_g)$).

R_t = Sum of grid leak resistance and effective resistance of load and internal valve resistance in parallel ($R_g + R . R_a/(R + R_a)$).

R_a = Internal (anode) resistance of valve.

r = Effective resistance of R and R_a in parallel.
$$= \frac{R.R_a}{R + R_a}.$$

C = Coupling capacitance in farads.

C_1 = Total shunt capacitance (including strays) in farads.

μ = Magnification factor of valve.

Typical Operating Conditions of Amplifiers.

The following table (from R.C.A. data) gives the amplification that can be obtained from a single stage, using the valve type specified with the circuit component values shown. The symbols used are explained in Fig. 9.

The figure for voltage gain refers to an output voltage of 5 volts. M = megohms.

Classification of Amplifiers.

An amplifying valve can be used under varying conditions of operation, depending on the portion of the anode-current/grid voltage characteristic selected. The most usual method is to apply negative bias to the grid so that the anode current when no signal is applied is the value given by the mid-point of the straight portion of the characteristic curve. The signal then causes the anode current to vary linearly (within the limits of the straight portion) with the change in grid voltage. This method of operation, in which the anode current flows at all times during the cycle of changes, is called *Class A* operation.

Other methods of operating are:

Class AB. The initial bias is increased so that the anode current is cut off for part of the cycle when the grid is strongly negative.

Class B. The valve is initially biased to the point at which the anode current is cut off. The current then flows only when the grid potential is less negative than its initial value.

Class C. The grid is biased beyond the ' cut-off ' point, and thus the anode current only flows for a portion of the operating cycle.

Cathode Follower.

This is a form of circuit in which part of the output load resistance is included in the cathode circuit of the valve, the input being applied between the grid and earth in the usual way. A signal voltage applied to the grid will appear in the same phase across the cathode resistance, and the cathode potential may thus be considered to follow that of the grid—hence the name.

Although the impedance of the input is high, the output impedance of the cathode follower is low (being equal to $1/g_m$, the mutual conductance of the valve), and this enables the valve to be matched to a low impedance output without the use of a transformer. The voltage gain from the cathode is less than unity, and the valve can be used only for obtaining power gain. Other advantages of this circuit are: the input and output circuits have a common earth connexion; the frequency and phase response are good; the input capacitance is reduced.

Bel.—A unit used in comparing two amounts of power P_1 and P_2, defined as the logarithm of their ratio. The commonly used sub-multiple is the *decibel* ($\frac{1}{10}$th bel).

$$N_{db} = 10 \log_{10} \frac{P_1}{P_2}.$$

It is important to note that the decibel is not an absolute measure of power, but can only be legitimately used when the conditions are adequately specified.

The decibel is also used to express a ratio of two voltages or currents, in which case:

$$N_{db} = 20 \log_{10} \frac{V_1}{V_2}.$$

Matching Loudspeaker to Valve.

In audio frequency circuits it is of great importance that the impedance of the loudspeaker be matched to the optimum load impedance of the power valve which supplies it. This is done by

means of an output transformer with its primary and secondary windings tapped to give a number of different ratios.

The correct ratio is found by referring to the maker's data on the output valve for the optimum load impedance and relating the speech coil impedance of the loudspeaker to the transformer ratio from the chart (Fig. 10).

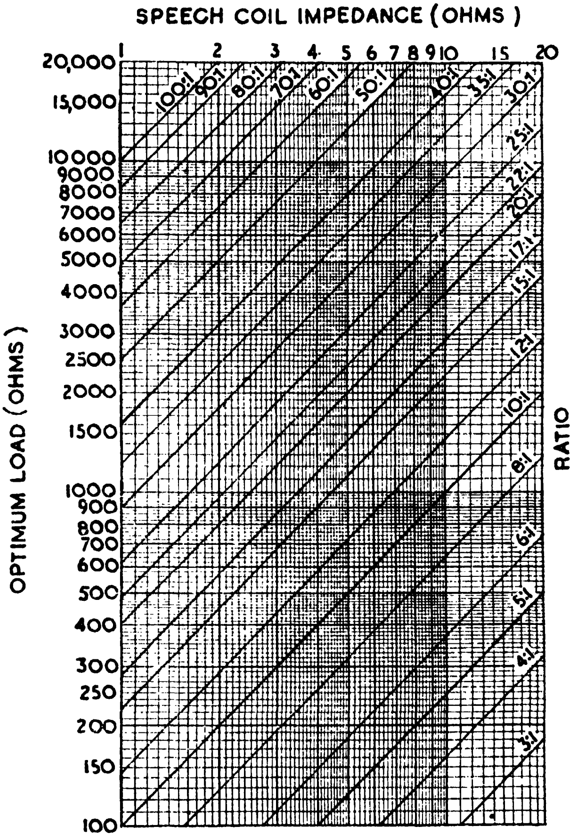

FIG. 10.—Chart for determining optimum transformer ratio between output valve and loudspeaker.

Purchasing.

As the making of paints, varnishes, japans, enamels and lacquers is a highly skilled industry dealing with a great variety of raw materials and finished products for use in widely different trades and processes it is essential that, lacking a comprehensive knowledge of the trade, a buyer should be explicit in making up his enquiries and orders. During the last fifteen years standardisation of products by specifications has advanced considerably, and for general purposes it is possible to quote standard specifications for the tints of the paints, etc., and for all the major ingredients, *e.g.* oils, pigments, varnishes, driers, solvents, etc., as well as for the finished products. The increase in the use of spraying, stoving and baking, dipping, etc., processes adapted for the use of enamels, japans, cellulose, lacquers and synthetic-resin enamels, working under a wide range of drying times and conditions of 'finish' emphasises the necessity of placing the supplier in possession of every possible item of information about the materials and processes required. Tests of materials should be carefully controlled and the results reduced to a properly arranged schedule of economic values against the price. For many special requirements in the protection and decoration of plant, products and buildings, etc., there are proprietary products of firms of high reputation that satisfy the purposes where ordinary paints, etc., would certainly fail. It is poor economy to buy paints, etc., on their price alone as the covering power (cost per square foot) and the durability or service and cost of application are governed by factors to which the price is not sufficient guide. Reference to the tables and lists of specifications, etc., given later will be found useful in comparing the values of coating compositions, etc. With the highly-skilled technical knowledge and research information at the disposal of the modern manufacturer of 'finishes' there is rarely any difficulty in securing products that are completely satisfactory in service and cost.

It is vitally important to bear in mind that the success or failure of paint, enamel, lacquer, or other coating composition depends as much upon the painter or the operator applying it and the conditions of application and drying as upon the paint, etc., itself, and the paint manufacturer should not be held to blame for every difficulty that arises in finishing processes until it has been proved beyond any doubt whatever that it is his material which is at fault. It will be found in practice, however, that the technical and service departments of the larger firms are always ready to co-operate in any painting problem, to reduce the possibilities of failure to the minimum.

Storage of Paints, etc.

Keep paints, varnishes, enamels, etc., in a cool dry store, away from flame or naked lights. See that all packages are securely closed when not in use to avoid loss of material, skins and contamination. Materials to which the Petroleum Acts, the Celluloid and Cellulose Solutions Regulations apply must be kept in fireproof, isolated and locked stores under responsible control and licence of the local Authorities. Buy paints in the most suitable and economical packages, *i.e.* common paints (red and white lead, zinc red oxides), oils, etc., in ½-cwt. drums; general-purpose paints, enamels, varnishes, cellulose and synthetic enamels in regular consumption in 1-gallon cans. Paints, etc., in occasional use should be bought in ½- or ¼-gallon cans. These smaller packages add little, if anything, to the cost and save much time and material in storage and handling.

Marking of Lead Paints.—Under the Lead Paints Act it is the duty of the *purchaser* to *instruct* the supplier to mark the packages to comply with the Acts. The supplier is not bound to do so without instructions.

Paste Paints should be kept covered with raw linseed oil (not water).

Distempers should be kept in a cool dry place (covered with petrifying liquid when necessary). Avoid exposure to frost or heat (above 80° F.).

Tints should always be checked before use. For large uniform surfaces, order sufficient of the colours required at one time or mix the contents of the several containers in one large vessel to ensure consistent shade.

Strain all paints, etc., taken from partly used containers to remove skins, etc., using metal gauzes wherever possible. In dip tanks and continuously operated plants regular clarification or straining of the paint by mechanical means is essential if finishes are to be obtained of the highest quality.

Thinners should be obtained from the maker of the material or to comply with the necessary specifications. Follow instructions carefully because many products, *e.g.* stoving japans, cellulose, lacquers, synthetic enamels, spirit varnishes, coach varnishes, are ruined by the addition of even small quantities of incorrect materials.

Brushes should be thoroughly cleaned in the proper solvents or thinners after use and hung up to dry or kept in the proper liquids between service. Never keep brushes in water; more painting troubles can be traced to moisture than anything else, and every care should be taken to avoid it. Old-fashioned painters still adhere to the practice when using white lead, but the results condemn the practice with other materials.

Distemper brushes should be thoroughly washed in hot soapy water and dried in a cool place hanging free in a current of air.

Flat rubber-set brushes of good thickness w'th medium length bristles give the best service.

Varnish brushes should be kept in thin varnish in a brush-saver between service.

Painting.

General Precautions.

All surfaces are to be cleaned free of dirt, rust, grease, scale and cracked or perished paint or tar. Perished paints are to be stripped off down to the bare surface by the use of blow lamp or liquid stripper. Blow lamp is best for plain surfaces, stripper for intricate detail or mouldings and glazed work—a combination of the two for painted plaster and very old enamelled work. The bare wood surface is to be made smooth, knotted with best shellac varnish, primed, stopped and filled before applying further paint. Bare steel should be scraped and scratch-brushed and primed with either special steel primer or red lead, etc.

Priming Paint for Wood.

Red lead or white lead with silicate fillers in refined linseed oil and high grade liquid driers and turpentine make good primers. Special paints of high quality are made by all good paint makers. Avoid water paints, glue and size compositions and common quick drying paints or mixtures of smudge residues as primers for outside exposure. Allow any paints to dry thoroughly before the next coats are applied. Aluminium powder mixed with high grade shellac varnish for knotting or with highly elastic waterproof oil varnish for general services provide excellent primers on American or Canadian pine woods where other kinds of priming paints prove unsatisfactory. On damp and unseasoned timber or under very moist conditions ethyl cellulose base primer lacquers are very valuable.

Priming for Steel.

Red lead, orange lead, white lead, blue lead, zinc dust, iron oxide and silicates, lead, zinc and barium chromates and other rust inhibitive pigments are good for steel in combination with refined and polymerised linseed oils, water-resisting varnishes and synthetic-resin media. The correct preparation of the oils and varnishes and the proper incorporation of the pigments with them to the right consistency is very important. Proprietary paints are based on long research and experience, and undoubtedly give the best results in marine, chemical-laden or tropical conditions. Bitumen solutions, particularly coal tar compounds or graphite, *i.e.* carbon black, vegetable black, lamp black and plumbago paints, should not be used alone as priming paints on steel. It is vitally important that all rust scale, dirt, grease and moisture be removed from the surface of the metal, and the loose rust scratch-brushed or treated with rust remover. Paints should be applied during the drier months of the year, *i.e.* June to September inclusive.

Spray Painting.

Spray Painting has very largely displaced brush application, especially in industrial finishing and the protection and decoration of large buildings and structures. Many types of spray pistol are available and the correct one should be selected for the paint or lacquer, etc., to be applied as the spreading power, viscosity, atomisation and drying of the paints, etc. are affected by the design and controls of the 'gun.'

For outdoor use, especially on steel surfaces, particular care has to be used in applying ordinary linseed oil paints as moisture condensed in the atomising air causes rapid corrosion under the paint surface. Special types of paints are made to minimise this fault.

The best working pressure lies between 45 and 60 lb., and for large surfaces a pressure-controlled paint container to feed the pistol gives quickest results. The spraying plants of the best known engineers are highly efficient and effect great economies in paint application. Paints containing lead oxide exceeding 5 per cent. of the pigment cannot be sprayed by women or young persons

and special regulations govern their use by men. As efficient leadless (maximum 5 per cent. lead oxide in the pigment) paints can be obtained in every required tint or finish, however, there is no obstacle to their use for every possible painting operation. Many novelty and special finishes owe their success to the use of spray plant in conjunction with conveyor drying and baking ovens.

Spraying Plant must be kept clean and free from dried paint or lacquer dust. Booths and fume pipes should be regularly scraped with brass scrapers and the clean bare metal coated with motor grease or soft soap. If newspaper is pasted on to the grease and coated with used motor oil the spray paint and dust will be easily stripped off when necessary. Walls and floors should be regularly freed from dust and dirt. Coat the walls with oil or grease and varnish or paint the floors to facilitate cleaning.

Pressure tanks should be blown out at the end of each shift, keep air lines and filters free of oil and water. Pistols should be kept thoroughly clean, allow to soak occasionally in strong solvent. Worn thimbles and needles should not be used.

Ventilation should be adequate—a good working standard is 5 changes per hour in the working room or space, and 75 cu. ft. per minute in the exhaust outlet of each booth. Remember that dust is drawn (from adjacent floors, windows, doors and cracks or crevices in roofs) into the spray booths by the exhaust draught.

Therefore to prevent spoiled work and unfair complaints about the paints, the access of dust must be prevented by every possible precaution and the removal of litter, etc. All lights and switches should be gasproof and totally enclosed. Stores for the paints, etc., should comply with the factory regulations applicable. Fire extinguishers and sand should be kept at hand in all stores and spraying rooms. Consult the suppliers of paints, etc., for information about the regulations which must be complied with in the plant and premises. Exits should be adequate and kept free from obstructions.

Stainers.

Stainers (tinting colours) should be purchased of good strong quality in semi-liquid form, packed in ½-gallon or ¼-gallon cans to ensure best and most economical results. The use of cheap paste stainers has nothing to recommend it.

High purity ochres, umbers, siennas, Venetian reds, Vandyke browns, yellow, brown, red and maroon oxides of iron, drop blacks, ultramarine, Prussian and Brunswick blues, chrome yellows and greens, lake yellows, greens, scarlets, maroons and other tints should be of the finest possible grinding, and lake colours should be permanent 'fast' shades. Do not expect 'fast' brilliant colours to be low in price and high in staining strength as well. Buy your staining colours as pure as you possibly can, use and store them carefully, and the results will be richer tints and better work at lowest possible costs.

Leadless Paints.

For many painting purposes high percentage lead pigments cannot be used, *e.g.* in sulphur-laden atmospheres, Food and Ordnance factories, Industrial processes employing women sprayers, interior decoration, heat-resisting finishes, and for certain colours. Therefore other suitable pigments have to be used. These are sometimes more expensive than lead pigments, *e.g.* titanium and antimony white oxides, cadmium yellow and selenium red sulphides, so that they cannot be called substitutes. Other pigments may be cheaper than white lead, *e.g.* lithopone, zinc oxide and reduced titanium oxide compounds, but they serve a sphere of usefulness for which white lead would be unsuitable in any case and too expensive. It is also a fact that there are many brilliant pigments which have greater permanence than any lead pigments, *e.g.* Prussian and ultramarine blues, zinc, cadmium and barium yellows, iron oxide yellows, cadmium selenium, orange and red pigments, Azo lake yellows, reds, oranges, scarlet, carmine and maroon colours, chromium and lead or zinc chromate. Greens and lake blues are also very permanent, and the addition of lead pigments to them is a detriment rather than an improvement. The range of iron oxides produced in such rich tints of yellows, browns, Venetian, Turkey and Indian reds and blacks are themselves far more permanent than lead pigments, and they do not need the addition of lead to brighten their colours or improve the covering power and durability. The technical research and advances made by the colour-making industry during the past thirty years have resulted in the production of new pigments which, in conjunction with the media resulting from intense research by the paint trade during the same time, now provide paints of greater durability under extreme conditions than could ever be provided by 100 per cent. lead-linseed-oil paints, and furthermore, the range of colours available is much wider than if lead pigments only were to be used. The old fetish of the superiority of white lead paint is steadily passing away and the spread of more knowledge of paint and painting materials is enhancing the confidence that the leadless paints can be used for exterior exposure. The use of leadless pigments for interior work has been absolutely essential for many years, and lead paints under such conditions are at a great disadvantage.

Paints for Aircraft.

The paints required have to be prepared under the most careful technical control, skilled testing and inspection to specifications which are among the most rigid in the paint, etc., industry. For obvious reasons the details cannot be referred to. The Departments concerned must be

referred to. The Departments concerned can supply the necessary information to bona-fide users. The principal paint manufacturers are usually familiar with the details of the specifications required.

Under civil conditions the B.S.I. Specifications for aircraft materials and components comprise the following :—

Paints and Dopes.

2D8.	Nitro-cellulose syrup.
4D100.	Air Ministry cellulose acetate dope.
D102.	Nitro-cellulose dope.
2D101.	Doping schemes.
2D103.	Nitro dope coverings and identification colours.
D105.	Pigmented nitro-cellulose dope.
4X2.	Oil and petrol resisting battleship grey paint.
3X4.	White dope-resisting paint.
3X6.	Varnish for external woodwork.
3X7.	Varnish for internal woodwork.
2X8.	Undercoating propeller varnish.
3X9.	Bituminous paint.
2X11.	Transparent woodfiller for propellers.
2X12.	Finishing propeller varnish.
2X14.	Priming varnish.
X16.	Undercoating grey paint.
2X17.	Seaplane varnish.
X18.	Shellac varnish.
X19.	Acid-resisting paint.

The ingredients of these paints and dopes are covered by a long list of 'D' specifications including solvents, plasticisers, pigments, etc. Full details of these can be obtained from the British Standards Institution lists. The Air Ministry Specifications comprise :—

DTD56B.	Stoving enamels.
DTD62B.	Pigmented oil varnish.
DTD63A.	Cellulose enamels.
DTD83A.	Seaplane dopes.
DTD103.	Air screw lacquers.
DTD145 & 157.	Identification colours.
DTD226.	Paint remover.
DTD235.	Stoving enamels.
DTD260A & 314.	Pigmented oil varnishes.
DTD308.	Cellulose finishes.

All these paints and enamels have been perfected after long research and experimental work and are produced under rigid technical control, continual testing and inspection. In addition to the above-mentioned paints there are very large numbers of special paints, enamels and compositions prepared and approved for special purposes, details of which, of course, are not available. It can be said without hesitation that the standard of paints and compositions and the skill and knowledge required to successfully produce them represent the highest standards in paint manufacture for large scale production, and that firms on the approved lists of suppliers can be relied upon for the unfailing quality of their products.

HEAT-RESISTING AND FIREPROOF PAINTS.

The composition of these paints varies according to the heat and conditions to which they are exposed, *e.g.* paints for smokestacks differ widely in composition from paints for treating woodwork which may be exposed to flame. For many years combinations of water glass with pigments which may be of the reactive type, combined with alkali borates, have been used effectively on wood and fibre constructions. Similarly, pigments produced at high temperatures, *e.g.* Indian reds, vegetable blacks, titanium whites, incorporated in media consisting of heat-treated oils and synthetic resins which polymerise on exposure to heat, together with combinations of bitumens of high melting points, are used for metal work exposed to high temperatures. The pigments are usually inert and refractory and comprise asbestos, kaolin, barytes, oxides of zinc and titanium with heat-resisting staining colours, *e.g.* ultramarine blues, vegetable blacks, cadmium yellows, selenium reds, chrome greens, aluminium powder, etc. In the event of fire the fire-retarding nature of the paint is more important than its colour or covering power, and the incorporation of ammonia compounds in the paints is often useful. For fabrics, canvas, hessian and cotton goods special dressing solutions containing borax, boracic acid, salammoniac, alum, alkali phosphates are employed. Solutions of cellulose ethers and cellulose acetates, chlorinated rubber and chlorinated resin compounds are now available in clear and coloured finishes which can also be applied to woodwork. These compositions, when properly compounded, do not burst into flame even under the worst conditions and are definite fire retardents.

Bituminous Solutions and Paints.

There are many 'bituminous' materials from which these solutions and paints are made and include coal tar and water gas pitches, petroleum pitches, natural bitumens and asphaltums, rosin and wood pitches, stearine pitches, etc. Solutions of these in solvents, *e.g.* coal tar naphtha and white spirit, with or without drying oils and gum resins constitute the 'Bitumen Solutions' of commerce, and they may be pigmented with oxides of iron, lead and zinc colours, chrome greens and fillers or extenders as may be required. Specially refined and decolourised bitumens or pitches which are a deep brown colour or the specially extracted resins from certain coal tar products may be used in the production of so-called light bitumen paints, *e.g.* white, cream, grey, etc. Actually, a completely decolourised or white bitumen does not exist, the palest of them being straw colour which darken on exposure to light. Therefore the palest colours (white, light greys, cream, etc.) cannot be made in genuine bitumen solutions. Such light colour bitumen paints, and indeed many of the darker colours, usually consist of a quick-setting elastic oil-varnish medium which includes varying proportions of bitumen varnishes with metallic oxide and silicate pigments. The natural black or dark bitumens and asphaltums are remarkable for their resistance to acids, alkalis and moisture, especially when properly compounded for application to wood or cast iron. The purity of the bitumen, its origin and its treatment, all combine to secure these durable properties. The covering power of bitumen solutions may reach 1,200 sq. ft. per gallon in the unpigmented types and 900–1,000 sq. ft. per gallon in pigmented qualities. They are usually cheap, easily applied by unskilled labour, and dry rapidly in any climate and by reason of their peculiar properties are ideal for many conditions, especially underground. The best grades contain 60–65 per cent. of plastic bitumen. Special types of bitumen solutions are prepared having great resistance to heat and are therefore suitable for industrial plants, boilers and pipelines. Long experience has shown that bitumen paints and solutions do not give the best results when applied direct as primers to steel surfaces, and that there is a small optimum amount of bitumen which may be incorporated in a paint which is to give service equal to that of the best quality oil varnish paints. Good priming paint made with metallic oxides, chromates and tough drying oil-varnish media, followed by the bitumen paints or solutions, are much better than bitumen paints alone. In any case bitumen paints have a much shorter durability than good quality oil paints, and should be looked upon as more or less temporary in their protection. Bituminous emulsions are prepared by the incorporation of special types of plastic bitumens with water in the presence of emulsifying and stabilising agents, with the addition of the necessary pigments and extenders to produce the colours required. They can be made in glossy or flat finishes, in rough or smooth textured surfaces, and for camouflage purposes are being used in enormous quantities, affording a cheap, fairly durable and easily applied substitute for linseed oil paints. For the treatment of cement surfaces they should be superseded by a special primer if the cement is new, but on old weathered brickwork, cement, plaster or asbestos sheets, two coats are usually ample, whilst on galvanised or painted sheets, steelwork, glass, wood and tarred roads, fabric, vegetation, etc., one coat is sufficient.

Red Lead Paints.

The advantages of the 'non-setting' types of red lead for making paints for steelwork are now universally appreciated.

Red lead complying with B.S.I. Specification 217A, containing about 25 per cent. lead peroxide, is largely used, although superior results are obtained by using the type B.S.S. No. 315 (217C/1936) containing about 32 per cent. lead peroxide. The old type of red lead which, owing to its rapid setting properties had to be used in conjunction with white lead to keep it workable for a reasonable length of time, is now largely confined to the preparation of red lead jointing pastes. It contains about 15 per cent. lead peroxide.

The only B.S.I. specification covering red lead liquid paint (ready mixed) is contained in B.S.I. Specification No. 153, and is given as follows:—

Red lead, B.S.S. No. 217A	33 lbs.
Boiled linseed oil	$\frac{2}{3}$ gallon.
Raw linseed oil	$\frac{1}{3}$,,

This material is very thin and does not give as good results as a mixture of 80 per cent. red lead to B.S.I. Specification No. 217A or C with 20 per cent. of raw or boiled linseed oil, with or without the addition of small quantities of turpentine or turpentine substitute. The covering power of red lead paints to the above specification is about 50 sq. ft. to the lb. and owing to the very high gravity (often 30–32 lb. per gallon) the use of 'Highly Dispersed' red lead is gradually gaining favour. These highly dispersed red leads are very fine in texture, of very high covering power, and produce paints weighing about 15 lb. per gallon containing up to 60 per cent. of oil which have the same covering power as the older types of red lead weighing 30–32 lb. per gallon. There is, therefore, a considerable saving in the weight of red lead used per ton of steelwork, and the anti-corrosive qualities of the highly dispersed red lead paint are superior to those of the older types. These new highly dispersed red leads are less prone to set or settle than non-setting types of red lead, and their greater use in the future is to be expected. Careful preparation and testing of the linseed oils for making red lead paints are very important, very low or

high acid value and over-boiling must be avoided. The old custom of melting a little *tallow in the oil* before mixing with the lead has much to recommend it.

A new specification, B.S. 1011 (with a War Emergency Revision), was issued in 1942, and covers two types: Type 1, for genuine red lead paint permits a maximum of 4 per cent. of extender to prevent caking; and Type 2 permits of extender not exceeding 15 per cent. Particular care should be exercised in selecting the kinds of extender used for these paints, or they defeat the object for which they are incorporated if of unsuitable quality.

White Lead Paints.

Genuine dry (basic hydrated carbonate) white lead should comply with B.S.I. Specification 239—1936, paste white lead should comply with B.S.I. Specification 241—1935, and ready mixed white lead with B.S.I. Specification 261—1936. Under a legal decision 'genuine white lead' may consist of white basic sulphate of lead. When ordering, the correct description should be specified to avoid confusion. In actual durability there is little difference, in fact on steelwork the basic sulphate gives superior results. It does not, however, permit of the liberties in use and making-up that do not affect the basic carbonate. The consistency of white lead pastes may be varied considerably to suit various markets.

Basic carbonate lead white mixed paint weighs about 28 lb. per gallon and covers 50–60 sq. ft. per lb. (1,500 sq. ft. per gallon or 6,000 sq. ft. (700 sq. yds.) per cwt.) on smooth hard-primed work. Lower figures must be taken for priming on wood and higher figures for tinted paints, *e.g.* grey paint covers 75 sq. ft. per lb. The average life of a white lead linseed oil paint (exterior, in town atmospheres) is about three years. White lead paint should be purchased in ready-mixed condition wherever possible. The heavy paste entails much labour in breaking down and results are not consistent.

A War Emergency Specification, B.S. 929, was issued in 1942 and amended in 1943, and includes Tinted White Lead Base Primer (929/P.1), White Lead Undercoating Paint (929/U.1), Tinted White Lead Undercoating Paint (929/U.4) Finishing White Lead Paint (929/F.1), Tinted Finishing White Lead Paint (929/F.5). Full details of composition for each type are given in the Specification.

It has been found that paints containing very low percentages of white lead in the light tints fail to pass the corrosion tests set out in this War-time Emergency Specification, and a minimum of 20 per cent. is desirable (as suggested in B.S.S. 1057/1942) for substitute paints for exterior finishing.

Gloss Paints and Enamels.

The combination of a finely divided pigment and varnish results in a coating with a glossy finish. The composition may vary from the cheapest Venetian red with the commonest 'oak' varnish used for painting gas pipes to the superbly ground and finished royal purple pigment in the highest grade enamel body varnish. Between the two extremes lie the hundreds of types necessary for the painting of houses, ships, transport vehicles, machinery, engines, steel-work, etc., each type requiring selected pigments and varnishes for its purpose.

Gloss paints and enamels effect a saving of time in application and give increased durability over finishes obtained by varnishing over flat colours and permit of more brilliant and attractive colours to be used. The covering power of gloss paints is very high—many cover 1,200 sq. ft. per gallon—the average being about 950 sq. ft. per gallon. They weigh from 12½ to 18 lb. per gallon according to tint and dry in 6 to 14 hours, covering solid at one coat. The best types are very durable, being superior to varnished work. They are made in lead base and leadless types. ENAMELS are heavy bodied, more elastic, slower drying types of gloss paints for interior use for very hard wear.

In the manufacture of the varnish media, high-grade copal gum resins, *e.g.* congo, animi, kauri, with refined and processed linseed and wood oils and the usual solvents and turpentine, or synthetic resins of the alkyd or phenolic types of special elasticity and durability give the best results for exterior work.

The production and processing of these materials require considerable skill and experience to yield highest grade products. Post-war conditions have restricted supplies of wood oils and certain synthetic resins of the phenolic types, but considerable research and practical work has been done to make use of other drying oils, *e.g.* processed castor oil. The resulting finishes are proving very satisfactory and have marked a new epoch in paint technology.

The same post-war shortage has also restricted the use of linseed oils and a number of pigments in paints, and therefore alternative specifications have been issued by the B.S.I. to cover other drying oils and pigments for wartime emergency use. Fuller details are given under 'Specifications.'

In 1943 specifications were issued for a number of paints, including Finishing Oil-Gloss (B.S.S. 929), Types F.1–F.14 inclusive, and B.S. 1056, Schedule 2, for specially hygienic finishes for hospitals, dairies, food factories, explosive factories, decontamination centres.

Owing to the control and restriction upon the use of certain pigments, oils, etc., it was not possible during war-time to produce gloss enamels of the high quality available prior to 1940, and the technique and methods of manufacture of these gloss paints and enamels had to undergo drastic changes.

Fuller information about these changes can be obtained by reference to B.S. Specifications 925, 926, 927, 928, 929, 1056 and 1057.

Paints for Woodwork.

The moisture content of building timber varies from 2 to 35 per cent. by weight. Successful paint for woodwork must therefore be capable of adhering to a surface that is continually changing in shape and porosity. The efficiency of white lead in the painting of wood is due to its capacity of retaining and discharging a considerable quantity of moisture without materially affecting the elasticity of the paint film. Zinc oxide on the other hand has no capacity for moisture and scales and flakes off badly as the film of paint is dissolved from behind. Titanium oxide has such intense surface energy that it passes through the binding medium and chalks badly. Lithopone forms an emulsion and is washed away eventually. Oxides of iron are the most inert coloured pigments, and when used in combination with thoroughly waterproof drying media give the most durable results. Lead chrome yellows, red and orange leads, lead base greens and blues are fairly stable, but the effect of the lead pigments on the drying oils reduces the durability. Lamp black pigments are durable if the drying is not forced, zinc base or lead base tinted whites (creams, greys, etc.) are very satisfactory if not reduced by the use of extenders in excess.

The addition of 5 per cent. or 10 per cent. of asbestine and up to 25 per cent. of silica or barytes is not detrimental to a pigment of high opacity and fine division.

Priming paints for wood should be made with double boiled (bodied) linseed oil and turpentine —be easily brushable and dry to a firm hard half gloss surface in 16 hours.

Undercoats should be eggshell matt, be tough and firm (not brittle) in 12 hours.

Finishing gloss paints or varnish paints, enamels or varnishes should dry dust-free in 4 to 6 hours, and be tough and elastic in 24 hours. Tests for varnishes are given in B.S.I. Specification Nos. 256 and 257—1936.

All the precautions with regard to buying, storage and application of paints given in the early paragraphs of this section should be observed in dealing with paints for woodwork. Every maker of repute *should* provide satisfactory paints for wood.

Painting Generally.

As very few of the old type of skilled craftsman painters who knew how to mix their paints properly for the work in hand are left in the trade, the application of paints, varnishes and enamels is now largely in the hands of semi-skilled labour or of men specialising in the use of 'proprietary' paints.

This is an era of ready-mixed paints, whether for brush, spray or dip application, problems of which have been solved by many paint manufacturers, each with a 'proprietary' material of its own for every particular purpose.

The semi-skilled painter, working under 'contract' conditions, demands easy-flowing, fast-drying, smooth finishes that require little rubbing down, have good opacity, and set tough and firm under almost all conditions. Under such conditions painting is lower in cost and factories, industrial plant, public buildings, houses, hospitals and institutions are kept in a better, more attractive and durable condition at a lower annual expense.

Conditions, however, can and do arise when ignorance or curiosity cause painters and those in charge of painting jobs to ignore certain basic principles of paint application and to meddle with 'proprietary' materials with which they are supplied, particularly if the contract price has been cut to very fine limits.

If, therefore, complaints are received about the behaviour of the productions of well-known firms, investigation should be very thorough. The condition of the wood or metal surfaces that have been treated, the weather conditions during application, the methods of application, and, above all, the treatment of the materials themselves, particularly as regard the addition of turps, spirits, boiled oil, paraffin, linseed oil, or the mixing of old 'overs,' and the care and maintenance of the brushes, spray guns, etc., employed, should be very thoroughly dealt with.

The Service Department of the modern paint manufacturer is a very efficient organisation, has a thorough knowledge of paint and painting problems, and can be relied upon not only to assist in obtaining the required finish and durability of its firm's materials, but also in counteracting any attempts at imposition or evasion in the obligations of the painting contractors.

Steelwork Paints.

This section of the paint industry has been the subject of the most intense research and trial during the last twenty-five years. The whole question of the cause of corrosion, its development and prevention have been the close study of technical and engineering bodies all over the world. The tests have proved the necessity of providing not only pigments of the required colour and opacity, but the inclusion of substances capable of preventing iron passing into solution in water and of converting the active iron compounds (hydroxides) into inert material within the binding medium used to form the film. As it is impossible to secure either a completely dry and rust-free iron or steel surface in general constructional steelwork practice, the importance of securing effective compositions for the protection of the steel can be understood. Thorough cleaning and scratch-brushing followed by treatment with paints containing iron oxides of high purity, red leads, lead chromates, zinc chromates, orange lead, basic white leads, blue leads, in oil-varnish vehicles, has been found effective. The most successful depended on the waterproof and elastic properties of their mediums. Linseed oil alone is not the best vehicle. Inert pigments such as graphite (plumbago), micaceous iron ore (Graphax), either alone or in combination with iron oxides, white lead, blue lead, zinc-lead oxide or aluminium powder have proved successful over satisfactory priming coats. The introduction of spraying plants has added to the problems of the steel paint chemist who has reinforced his media with synthetic resins to solve the difficulty. The value of properly made primers and protective coats has been realised, and there is not the cheese-paring of prices that was prevalent years ago. The best types of steel paints will ensure certainty of results under conditions which would be fatal to the old style red or white lead, linseed oil or oxide paints that were the stand-by of all engineers. The pre-treatment of the steel by chemical de-rusting compounds is now a recognised process in steel painting. The use of baked primers and finishes on portable parts in the sheet metal industry demanded such metal-cleaning material, and the method has extended to constructional work on a large scale. The next step was to include rust-converting compounds in the paint itself, and this is now the basis of a well-known patent. The life of steelwork paints of the best quality can be averaged at five years. Highly efficient paints and gloss enamel for every type of steelwork can be procured from the established firms, but in spite of many years work and research no universally satisfactory specification has yet been issued for gloss paints for steelwork.

Specifications of Paints, etc.

Nearly a thousand specifications for paints, pigments, oils, lacquers, varnishes, enamels, compositions, colour tints, etc., are issued by the British Standards Institution, the Government departments, railways, shipping companies, corporations, engineers and architects, the British Colour Council and professional bodies.

The majority of paint requirements are covered by specifications, but many important materials are not yet covered. Reliance can be placed on the products of well-established firms for the special materials, and information about standard specifications can be usually obtained freely from them. The B.S.I. specifications most frequently required by engineering contractors for paints are as follows:—

B.S.S. No. 197.	Black oil pastes, Grade 1, Grade 2.
B.S.S. No. 217.	Red lead, dry, for paints, Types A, B and C.
B.S.S. No. 239.	White pigments for paints. Genuine basic carbonate of lead.
B.S.S. No. 254.	Zinc oxide, Types 1 and 2.
B.S.S. No. 296.	Lithopone.
B.S.S. No. 338.	Antimony oxide.
B.S.S. No. 392.	Titanium dioxide.
B.S.S. No. 636.	Titanium white.
B.S.S. No. 637.	Basic sulphate of lead.
B.S.S. No. 241.	Genuine white oil pastes for paints.
B.S.S. No. 273.	Zinc oxide oil paste.
B.S.S. No. 297.	Lithopone oil paste.
B.S.S. No. 242.	Linseed oil, refined.
B.S.S. No. 243.	Linseed oil, raw.
B.S.S. No. 244.	Turpentine, Type 1.
B.S.S. No. 245.	White spirit.
B.S.S. No. 290.	Turpentine, Type 2.
B.S.S. No. 256.	Interior oil varnish, Types 1, 2 and 3.
B.S.S. No. 257.	Exterior oil varnish, Types 1, 2 and 3.
B.S.S. No. 258.	Flatting or rubbing oil varnish, Types 1 and 2.
B.S.S. No. 274.	Extra hard drying varnish, Types 1 and 2.
B.S.S. No. 259.	Boiled linseed oil.
B.S.S. No. 261.	White lead ready-mixed paint.
B.S.S. No. 262.	Tinted ready-mixed white lead paints, Types 1 and 2.
B.S.S. No. 277.	Zinc oxide base white ready-mixed paint.
B.S.S. No. 278.	Zinc oxide base tinted ready-mixed paints, Types 1 and 2, Grade L and H.
B.S.S. No. 293.	Green ready-mixed paints, lead chromate base, Types 1, 2, 3 and 4.
B.S.S. No. 294.	Black ready-mixed paints, Types 1, 2 and 3.

B.S.S. No. 295. Red oxide of iron ready-mixed paints, Grade L and H.
B.S.S. No. 371. Purple brown red oxide of iron ready-mixed paints.
B.S.S. No. 381. Colours for ready-mixed paints.
B.S.S. No. 391. Tung oil for paints.
B.S.S. No. 654. Perilla oil for paints.
B.S.S. No. 298. Red oxide of iron oil paste, Class 1. Natural or mixed oxides.
B.S.S. No. 299. Red oxide of iron oil paste, Class 2. Oxide of iron base.
B.S.S. No. 303. Brunswick green for paints (pure and reduced).
B.S.S. No. 304. Brunswick green oil paste for paints (pure and reduced).
B.S.S. No. 311. Varnish gold size.
B.S.S. No. 337. Ochre for paints.
B.S.S. No. 331. Paste driers.
B.S.S. No. 332. Liquid driers.
B.S.S. No. 388. Aluminium (powder and paste) for paints.
B.S.S. Nos. 390 and 393. Oil pastes. General colours.
B.S.S. No. 544. Linseed oil putty, Types 1 and 2.
B.S.S. No. 3011. Paints. Identification for engine-room piping.
B.S.S. No. 954. Shellac.
B.S.S. No. 284. Black carbon pigments.
B.S.S. No. 285. Bone black.
B.S.S. No. 286. Vegetable black.
B.S.S. No. 287. Lamp black.
B.S.S. No. 288. Mineral black.
B.S.S. No. 272. Natural red oxides of iron.
B.S.S. No. 305. Manufactured red oxides of iron.
B.S.S. No. 695. Blended oxides of iron.
B.S.S. No. 306. Black oxide of iron.
B.S.S. No. 339. Purple oxides of iron.
B.S.S. No. 851. Yellow oxides of iron.
B.S.S. No. 370. Venetian red.
B.S.S. No. 312. Sienna.
B.S.S. No. 313. Umber.
B.S.S. No. 319. Vandyke brown.
B.S.S. No. 282. Lead chrome yellow.
B.S.S. No. 389. Zinc chrome yellow.
B.S.S. No. 318. Chrome oxide greens.
B.S.S. No. 383. Prussian blue.
B.S.S. No. 314. Ultramarine blue.
B.S.S. No. 333. Lake red pigments.
B.S.S. No. 320. Mercury vermillion.
B.S.S. No. 987. Camouflage paints.
B.S.S. No. 1011. Red lead paints.
B.S.S. No. 1033. Priming paints lead-base (Types 1, 2, 3, 4 and 5).
B.S.S. No. 1053. Water paints and distempers.
B.S.S. No. 1056. Painting of buildings in wartime.
B.S.S. No. 1057. Substitute paints for exterior finishing.

War Emergency Paints.

B.S.S. No. 925. Paint oils.
B.S.S. No. 926. Extenders for paints.
B.S.S. No. 927. Alternatives for lead and zinc chrome yellows.
B.S.S. No. 928. Alternatives for chrome greens.
B.S.S. No. 929. Ready-mixed paints, priming, undercoating and finishing.

In addition to the above specifications there are, of course, many others which cover the ingredients, *e.g.* Prussian Blue No. 283; red lakes, No. 333; vegetable black, No. 286; red oxide of iron, dry, Nos. 272, 305 and 694. The index of the B.S.I. Handbook should be consulted for fuller details.

VARNISHES (OIL AND SPIRIT).

Of all the painting materials used by the engineer, varnish can be the most troublesome.

For decorative and protective purposes the B.S.I. specifications cover three interior types, B.S.S. 256—1936, types 1, 2, 3; and three exterior types, B.S.S. 257—1936, types 1, 2, 3. The latter may be used for other purposes, *e.g.* transport vehicles, engines, machinery, etc., in conjunction with flatting varnish B.S.S. 258—1936, and extra hard drying varnish B.S.S. 274—1936. For special purposes it is best to buy correctly prepared products which comprise heat-resisting, oil, petrol, and benzol-proof; alkali and acid-proof, suds-proof, gas-proof, di-electric, anti-rust and moisture-proof varnishes, baking varnishes, etc., cements and gold sizes (B.S.S. 311—1936).

The gums and resins may be of natural origin or produced synthetically or a combination of the two in conjunction with drying oils, solvents and plasticisers and chemical compounds.

Synthetic and artificial resins have reached a high state of perfection, ensure reliable results and effect great economies in production times. The insulating varnishes made from the phenol-

cresyl formaldehydes and the glycerine-phthallic anhydride resins and their compounds are used in enormous quantities in the engineering trades.

Spirit varnishes are made from seed lac, shellac, garnet lac, bleached and refined lacs, natural and synthetic resins and plasticisers and balsams with the addition of rosin, fatty oils (castor oil), drying oils, etc. These are dissolved in methylated spirits, butyl and amyl alcohol, naphtha, benzol, acetone and other organic solvents with dyes and pigments. Combinations of these mixtures can also be made with nitro-cellulose, celluloid and other cellulose compounds to produce special types of lacquers.

'Hot' lacquers contain methylated spirits as the main solvent, whilst 'cold' lacquers are made by substituting higher boiling solvents for part of the methylated spirit to ensure freedom from moisture absorption ('water-blush') during drying.

DISTEMPERS, WATER PAINTS, EMULSION PAINTS.

Aqueous solutions of glue, casein, Irish moss, water-soluble gums and resins, with soaps made from drying oils, drying oils and gum resins in the form of stable emulsions are the bases of these paints.

The cheapest consist of glue-size and whiting made in jelly form and treated with preservatives to prevent decomposition. The best contain little, if any, glue or casein, consisting mainly of lithopone, earth and lake colours, drying oils and resins in an aqueous emulsion.

Modern types have great covering power and resistance to wear; are very stable and consistent in quality. The decorative effects are of a very high order, especially when applied by spraying.

CELLULOID AND CELLULOSE SOLUTIONS REGULATIONS.

Under 'Cellulose Solutions, S.R. & O. 990 (1934)' and 'Cellulose Regulations 980 (1925)' the use, storage and manipulation of celluloid in solid and liquid form and of cellulose solutions in clear or pigmented condition are placed under strict control and inspection by the Home Office Factory Department.

The storage of the raw materials and finished solutions or enamels, the processes of production, the application of the enamels and lacquers to industrial materials in factories or workshops and the maintenance and repair of the buildings and plant in which the production, use, manipulation or application of these solutions and enamels are carried on, including the provision and maintenance of the necessary exits from the spraying, painting, mixing and storage places and rooms and the ventilation, heating, lighting and cleaning of such places are all governed by these Statutory Orders and Regulations. A copy of the Regulations must be kept posted in the proper places and reference should be made to the Factory Inspector and to the Memorandum on the use of Cellulose Solutions issued by the Home Office. Suppliers and manufacturers of cellulose products will assist with the necessary information where possible to ensure that the users will conform to the Regulations laid down. It must also be borne in mind that as cellulose lacquers usually contain petroleum mixtures having flash points below 73° F. the storage, use and transport of them is governed by the Petroleum Acts and that the local Petroleum Inspector has the right of entry and examination under the powers conferred upon him by statute. The Petroleum Acts and the Regulations issued thereon should therefore be consulted as well as the Cellulose Regulations and Factory Acts. The painting of buildings (including the internal decoration of cinemas, restaurants, etc.), is expressly excluded from the operations of the Cellulose Solution S.R. & O. 990 (1934).

LEAD PAINT REGULATIONS.

The following Rules and Orders and Regulations are at present in force under the Factory Acts and Lead Paints Act:—

Paints and Colours, Manufacture of, 945
Lead compounds, Manufacture of, 979, 996, 1713, 1714.
Painting of Buildings, 995 & S.R. & O. 847.
Painting of Vehicles, 994.

These regulate the rubbing down of dry paint films, the spraying of paints, the use of overalls, washing appliances, medical examinations and employment of women and young persons, dust extraction, etc., and should be consulted for details as failure to comply with them involve penalties on employers and employees.

PAINT ECONOMY MEMORANDUM.

The Interim Economy Memorandum issued by the Ministry of Works in September 1946, has now been reviewed in the light of present day conditions. Whilst raw material shortages are not so acute as in 1946, linseed oil supplies involve heavy expenditure of hard currency and this makes it necessary to continue to economise, wherever possible, in its use. The Schedule in the previous Economy Memorandum has been withdrawn and the following recommendations issued in its place:

1. Paints containing linseed oil should not be used in maintenance work for repainting surfaces which, by cleaning or other reasonable treatment, can be restored to a condition appropriate to the purpose for which the room or building is about to be used.

2. Paints, or other treatments containing linseed oil should not be used on exterior surfaces, previously unpainted, of stone, brick, clay-block, concrete cement rendering or stucco.

3. Paints, or other treatments, containing linseed oil should not be used when re-painting surfaces previously treated with cement paints, silicate paints, bituminous paints or wood preservatives.

4. Bituminous or tar paints should be used wherever practicable on exterior iron and steel such as gates, railings, outbuildings, etc.

5. Wood preservatives, in place of paint, should be used wherever practicable on exterior woodwork such as weatherboards, bargeboards, gutterboards, outbuildings, etc.

6. Encouragement should be given to the use of stain and varnish, in place of paint, wherever practicable on interior woodwork such as doors, cupboards, architraves, picture rails, skirtings and staircases.

7. Cement paints, or silicate paints should be used where suitable, according to the type and purpose of the building, on interior surfaces of brick, concrete, cement rendering, asbestos-cement, lime plaster and insulating board.

Linseed and other Drying Oils.

Linseed oil has been used as a paint medium for thousands of years. Its preparation and uses have been the objects of generations of research.

Intensive study of its technology during recent years has resulted in improved paints, varnishes and enamels. The raw linseed oil of commerce, containing mucilage, foots, water, free acid and albuminous materials, is not fit for the preparation of high quality paints, etc., until it has undergone prolonged tanking to settle out some impurities and render it mature, or has been subjected to one of the several refining processes (cracking by acid or alkali, de-sliming by siliceous earths, neutralising by glycerine) or treatment by heat alone. Clarification by filter-pressing, centrifuging or tanking followed by washing and neutralising result in 'refined' oil. Linseed oil is extracted from seed produced in Western India (Bombay oil), Eastern India (Calcutta oil), Argentina (Plate oil), Finland and Esthonia (Baltic oil). Baltic oil of the 1913 type was considered the acme of quality for best quality varnishes and enamels, but the quality depreciated badly following the Russian revolution and has not yet regained its former reputation. Calcutta oil is the most widely used for varnish, enamel and high grade paints. Plate oil is mainly used for cheap paints and white enamels as it bleaches easily.

Linseed oils are subjected to heat treatments to produce 'Boiled' and 'Double Boiled' linseeds on combination with rosinates, linoleates, naphthenates, oxides, acetates and hydrates of lead, cobalt, zinc, magnesium and manganese.

Polymerised linseed oils (stand oils or litho oils) are produced by heating the specially prepared oils at 550–600° F. for 4–24 hrs. or for 20–60 mins. at 700° F. in special plants. These oils are thick and heavy in body, dry slowly but impart durability and elasticity to varnishes, etc. Linseed oils can be thickened by heating and blowing with air or oxygen or chemical treatment to yield oil of special interest in spraying, plastic, linoleum-wet-on-wet, and wall finishes. The linseed oils are used in many forms either alone or in conjunction with Chinese wood oil (Tung oil, B.S.S. 391—1929), soya bean oil, fish oils, perilla oil, castor oil, oiticica oil, and natural (fossil) resins, synthetic and artificial resins, pitches, driers, turpentine and white spirits or other solvents to produce varnishes, japans, enamels and gloss paints for hundreds of purposes.

The specifications for linseed oils are :—

Raw linseed oil . . .	**B.S.S. 243—1926.**
Refined linseed oil . .	**B.S.S. 242—1926.**
Boiled " " . .	**B.S.S. 259—1926.**

To economise in the use of linseed oil during war-time, its use was rigidly controlled for even essential war purposes and prohibited for many 'civilian' uses. Tung oil, Perilla oil, Oiticica oils and treated castor oils were reserved for highest priority work only. Mixtures of linseed oils with other drying oils, *e.g.* fish oils, vegetable oils (except those referred to above), aromatic petroleum extracts (liquids and solids) were provided for in Government Specifications, *e.g.* B.S. 925/1011/1056/1057. Linseed oil was also partly or wholly replaced in oil-bound water-paints, and bituminous-emulsion camouflage paints even for Government work.

To meet the demand for drying oils to replace Tung, Oiticica and Perilla oils necessary for durability and resistance to solvents, chemicals, etc., in war finishes very thorough investigations into methods of processing linseed and other oils were undertaken and new types were successfully produced for use with imported natural and home produced synthetic resins.

Turpentine, White Spirits, etc.

Best American (spirits of) turpentine is distilled from the gummy exudation of pine trees, leaving rosin behind in the stills. It should comply with B.S.S. 244, Type 1, and occasionally turpentine of Indian, Swedish, French and Spanish, Greek or Russian origin may pass this specification. In general these other turpentines may comply more with the specification for the extracted wood turpentine (B.S.S. 290—1929 (Type 2). For painting purposes, polishes, etc., all are suitable, but for varnishes and veterinary purposes, best American turps (B.S.S. 244—1926 (Type 1) should be asked for.

White Spirits (Turpentine Substitutes).—For diluting paints made with linseed oil, white spirit of good quality is frequently mentioned in B.S.I. and other specifications. It is not advisable to use white spirit alone in paints containing varnish, stand oil, boiled linseed oil, japans or gold size, as the solvent power is poor. Turpentine should be added to the white spirit to ensure good mixing. There are several types of white spirit, one of them, B.S.S. 245—1926 (Type 1), being generally satisfactory for ordinary work. White spirit of good quality should leave no stain on clean filter paper and no residual odour after 1 hour's drying at 60° F., besides complying with other details of the specification. For painting indoors it is always advisable to use best turps whenever possible.

Solvent Naphtha (*Coal Tar Naphtha*) is largely used for thinning bitumen solutions and paints, rubber solutions and compositions. Two types are in general use, viz. Low Flash (90/160), B.S.S. 479A, and High Flash (90/190), B.B.S. 479B. These solvents are important as they are essential for the correct working of many painting compositions. Owing to the changes taking place in the treatment of coal for gas-making, crude oil for oil distillation and the economics of natural bitumen production, the character of bituminous solutions and paints is undergoing important changes.

Cellulose, Lacquers and Enamels.

Cellulose Lacquers and Enamels.—Treatment of cellulose (cotton, paper, wood fibre, vegetable matter) by acids (nitro-sulphuric and acetic) yields cellulose nitrates and acetates which are compounded with camphor, resins, plasticisers, gums, oils, solvents and diluents, pigments and dyes to produce cellulose lacquers and enamels for a great variety of purposes. Types differ for exterior (building and transport vehicle) and interior (building, hardware, fancy goods, machinery, furniture and domestic articles). Application is usually by spraying and great speed of finishing is possible. Modern types show exceptional resistance to sunlight, hard weather, abrasion, chemical action, heat and moisture. An immense number of types is available in the most brilliant and durable of colours. The types of 'cotton' are high, medium and low viscosity in 'ester' and 'spirit' soluble grades, and these are dissolved in combinations of organic solvents (alcohols, esters, ketones, ethers) with aromatic hydrocarbon diluents (toluol, xylol, benzol) and aliphatic hydrocarbons (ligroin, petroleum spirit, etc.). Synthetic resins and plasticisers are used in the most satisfactory types of lacquers to secure adhesion and toughness combined with durability.

The cellulose ethers (ethyl, methyl and benzyl, amyl and propyl celluloses) have special uses in industrial finishes. Methyl cellulose is the basis of modern water-bound plastic and texture paints, distempers and sizes.

The majority of the solvents, diluents, plasticisers, etc., used in the manufacture of cellulose lacquers together with some of the pigments are covered by B.S.I., 'X' or D.T.D. specifications. Numbers can be obtained from the standard index.

Synthetic Resin Varnishes and Enamels.

From the research and practice devoted to the phenol-formaldehyde spirit-soluble 'true' synthetic resins in the early years of the twentieth century have sprung legions of synthetic resins available to paint, varnish, lacquer and enamel users. There are three main types: phenol-aldehyde, cresol-aldehyde and xylenol-aldehyde (oil and spirit soluble), glycerine phthallic-anhydride (glyptal-oil-modified and spirit soluble), urea-formaldehyde (spirit soluble), coumarone, petroleum, vinyl and acrylate resins. In the original types 'mixed phenols' (carbolic acid) was used in conjunction with formaldehyde. Progress in technical knowledge has added considerably to the types available and the variations in the resins and their combinations that can be produced. The phenolic oil-soluble types yield varnishes of extraordinary resistance to sunlight, heat, hard weather, sea-water acid, alkali, oil, petrol and abrasion. The spirit-soluble types yield lacquers of exceptional di-electric strength, couparone and petroleum resins being unaffected by dilute acids and alkalis, have special applications in industrial and building coating compositions. Vinyl and acrylate resins being water white of perfect transparency, and unaffected by ultra-violet rays, have special technical uses. 'Modifications,' usually by adding rosin and resinates, are frequent and cause many complications. From the 'glyptals' are produced interior and exterior varnishes and enamels of especial durability and gloss for quick air-drying and baking purposes whilst the 'urea' resins yield enamels and lacquers of exceptionally pale colour, polymerising in very short times (15 min.) at 200–300° F. to very hard, tough and heat-resisting films. The combinations of all three types have special uses and provide a great variety of coatings for insulating, decorative, chemical proof and hard wearing service. The addition of the proper oil-soluble types of synthetic resins to linseed oil paints, varnishes and enamels ensures improved durability, higher gloss, greater protective power and durability and increased resistance against moisture and sunlight with the addition of speedier drying properties.

Stoving Japans, Enamels and Varnishes.

Natural, synthetic or artificial resins combined with drying oils, plasticisers, solvents, pitches, asphaltums, etc., yield coating compositions that can be baked or stoved at 75–500° F. in from 5–200 mins. after application by spraying, brushing or dipping. The composition of the japan or enamel is adjusted to the method and speed of production used, and the price available. The

work should be cleaned free of grease, oil and rust by the use of solvent, boiling caustic or de-rusting solutions, painted, drained, baked and cooled. One-coat work is general, two- or three-coat is the best. Box ovens are being replaced by 'conveyor' or 'tunnel' ovens through which the work is passed by chain conveyor systems. Heat is applied by either closed steam pipes, Bunsen gas burners, gas, coke or oil-fired 'plenum' (hot air) systems, infra-red (gas elements or electric lamps) and electric radiant elements. Steam, gas, electric and oil fired 'plenum' systems are all successful in their special spheres. Short exposure at a high temperature is possible with the quick polymerising (urea-glyptal) types of resin vehicles, white enamels being successfully baked at 600° F. in 3 mins. to hard durable finishes in modern infra-red stoves. Temperatures of 500° F. for 15 mins. are usual for black hardware japans. Baking types of cellulose enamels and synthetic resin enamels are used in vast quantities in the finishing of motor cars, hardware, toys, cycle and motor parts and accessories, etc. Food cans are treated with stoving finishings that resist bending, abrasion, weak organic acids, alkalis, sulphur compounds, sugar, superheated steam and weak alcohol and salt solutions. 'True' synthetic resins are expensive materials which provide distinct advantages over ordinary stoving enamels in drying time, finish, gloss, colour and resistance to modern conditions of hard wear, weather, etc. Unfortunately the temptation to substitute cheaper and less efficient materials at slightly less than the 'true' synthetic prices has resulted in dissatisfaction and suspicion of 'synthetics' generally. Careful tests will prove the economy and value of the highest grades.

Paint Shades and Colour Tints.

About eighty standard tints are recorded in the B.S.I. 381C specification. In addition the colour standard catalogues of the British Colour Council and Colour Users Association should be consulted for others.

These standard colour tints are a great help to both maker and user as colour names are to some extent brought into line for the first time.

Insulating Varnishes.

Quick air-drying types are made with spirit-soluble resins of high grade, *e.g.* refined shellacs, fossil resins, natural, synthetic and polymerised resins, pitches, cellulose acetate, with castor oil, Venice turps, synthetic plasticisers and the usual range of alcohols, ketones and hydrocarbons. These are also referred to sometimes as 'anti-sulphuric' enamels and are used for accumulators and battery room fittings. These varnishes are often lightly baked and can be applied to metal, fabric, cotton covering, paper, glass, vulcanite, etc.

Slow air-drying or baking types are prepared from 'phenol'-formaldehyde bases, glyptals or 'urea' resins either alone or combined. Natural fossil resins are chemically treated and combined with linseed, wood, perilla and fish oils or the oil-soluble synthetic resin varnishes to produce pale insulating varnishes.

Bitumens, asphaltums, pitches, etc., are added with or without waxes to produce the black insulating and impregnating types.

The vacuum-immersion type of application is essential for best results. Baking times vary from ½ hr. at 250° F. to 12 hrs. at 120° F. according to the varnish used. The B.S.I. Specifications are No. 514 (baking bitumen type) and No. 119 for clear baking oil varnish, for the varnished paper and tubes B.S.S. 316 and for varnished cloth or tape B.S.S. 419.

Chemical Resistant Enamels.

Natural resins, gums and oils are readily attacked by many chemicals, etc., and need reinforcement by other materials for improvement to resist even weak chemicals. The processes involved in the manufacture of synthetic and artificial resins pointed out the directions in which more satisfactory results could be found and the combination of these resins, etc., with polymerised oils (wood oil, castor oil, perilla oil) waxes, rubber and bitumens has yielded a long range of products giving satisfactory results. Modern finishes include air-dry and baking types of petrol and benzol proof enamels and varnishes; oil and grease proof enamels and varnishes; acid and alkali proof enamels and varnishes; sulphur-vapour proof enamels and varnishes; poison-gas proof enamels and varnishes; sea and soapy water proof enamels and varnishes; steam and moisture proof enamels and varnishes; ultra-violet proof enamels and varnishes; fungus proof enamels and varnishes; alcohol and solvent proof enamels and varnishes; heat and frost proof enamels and varnishes. They provide efficient protection in a large variety of circumstances for which ordinary types of paints, varnishes and enamels would be quite unsatisfactory.

Rust-Removers.

Pickling in solutions of sulphuric acid, oil of vitriol (hot solutions), hydrochloric acid (muriatic acid or spirits of salts), hot or cold, is the process generally used in large-scale practice. A water-swill followed by a neutralising wash follows and then drying or further treatment is given.

For delicate work *in situ* or for small rust spots on large surfaces, the use of phosphoric acid base washes has become general. There are many types covering varying concentrations of acid, different solvents, metallic salts and acids and colouring matters. Some need washing off with

water or solvent after the rust is dissolved, others can be left as they dry. Patents cover the best-known types.

These rust-removers or rust solvents are essential in modern painting practice on steel surfaces (*e.g.* motor bodies, steel furniture, car wheels and accessories and hardware), as they are speedy and quite safe.

Rust-Preventers.

After cleaning the surface of the steel, a rust-preventer should be applied at once. It may be oil, grease, petroleum jelly, varnish, paint or slushing glaze. There are many proprietary materials of great merit. Compounds of wool grease (lanoline) have been marketed for many years and can be obtained in a full range of drying and non-drying compositions. Specifications issued by Government departments and the National Physical Laboratory govern the properties of the wool grease and solvents used.

Paint Removers.

The saponifying power of caustic potash or soda and lime was the basis of the old type of paint remover and for rough work a mixture of soft soap, slaked lime and washing soda applied in paste form is effective.

The powerful solvents available in the cellulose industry form the basis of modern paint removers. Combinations of solvents exert more powerful action than single solvents. High volatility renders them ineffective, so slow drying solvents and retarders are used to keep the solvents in contact with the work long enough to be effective. The solvents used are acetone, ketones, benzol, naphtha, naphthalene, methylated spirit, di-chlor-ethylene, methylene chloride methyl alcohol, etc. The retarders are either lime or soda soaps, gums or resins, rubber, cellulose acetate, glucose, paraffin wax, stearine or glue with ammonia or acetic acid. The best types will strip stoved enamel in 5 mins. per coat and ordinary paint or cellulose 'at sight.'

It is important to follow strictly the makers' instructions about removal of the old paint and treatment of the stripped surface before repainting. Caustic alkalis, lime, wax and grease or spirit-soluble compounds may damage the new paint if left in cracks or crevices of the surface.

Covering Powers of Paints.

Specific Gravities of Paints.

The following tables are reproduced by permission of Thomas Howse, Ltd. The figures marked with an asterisk indicate paints which cover solid and completely obliterate the surface at the spreading rate given.

Metallic Paints.

Metal-powders (viz. aluminium, copper, brass, gun-metal, etc., are mixed with drying vehicles and applied to metal, wood, paper, fabric, etc., surfaces by spraying or brushing, etc. They may be baked or air-dried. The vehicles may be oil-varnishes, cellulose, lacquers, etc., of special types. Many types are prepared differing in their use. Some can be mixed with the metal powder and remain unaffected for weeks, others must be used immediately or the powder is attacked and loses its brilliance.

Aluminium Paints.

For resisting heat the synthetic resin types are satisfactory. For pipelines, machinery, factory plant and equipment, vehicles and hardware, street lamps, etc., the types vary considerably.

The best qualities weigh about 10 to 12 lb. per gallon, cover about 1,000 sq. ft. per gallon (sprayed) per coat. Drying times are from 5 mins. to 12 hours at 60° F.

Copper and gold bronzes require special mediums if they are to be kept in liquid form for even a few hours. They tarnish rapidly on exposure and do not resist temperatures as high as those at which aluminium is stable.

Particular care should be taken to avoid mixing metal powders with linseed oils, turpentine, copal varnishes or driers.

Painting Galvanised Iron.

The pickling processes used in preparing the sheet iron before galvanising result in the formation of corrosive zinc salts (chlorides and sulphates) on the spelter surface. Removal by washing or rain (weathering) after erection is the cheapest method and as safe as any.

Treatment of sheets that cannot be weathered (*e.g.* sheet-metal plant) must therefore include some neutralising process.

Washing with a mixture of hot water and methylated spirit is good—drying is speedy and natural as well as effective. The addition of phosphoric acid to the wash is a decided advantage. The best results are obtained by the use of the rust-removers used on rusty steel (mentioned in this section). When diluted with 5 to 10 times their volume of cold water they provide a splendid etching, cleaning and neutralising solvent for the zinc salts. Water soluble synthetic resins of the glycerine-phthallic-anhydride-urea type which are susceptible to the catalytic action of zinc salts are said to form hard and impervious coatings on zinc surfaces.

Good quality red oxide or bitumen paints or the well-known brands of steel primers are satisfactory paints for galvanised sheeting. They should be repainted at least once in every five years. The use of finely divided metals as pigments in liquid coatings has much to recommend it.

Paints for Cement, Concrete, Plaster and Asbestos Cement Surfaces.

Free lime is a necessary evil in the formation of the surface; disposal of it, or, rendering it inert within the texture of the surface is essential if the coating composition is to be permanent.

The formation of water-insoluble lime compounds is an attractive method of treatment and when aluminium and zinc salts (sulphates, fluorides) can be used there is a good chance of success. There is no hard and fast rule—each case can be dealt with on its merits, but a safe preparatory treatment for plaster consists of washing down with a 4 oz. per gallon solution of ammonia-alum (it must *not* be potash alum) repeating at 4 hours, drying off and dusting down after 24 hours. Cement, concrete and asbestos cement require stronger solutions. The preparatory sealer coat is of vital importance and too much care cannot be given to selecting a satisfactory make and following instructions fully. Combinations of unsaponifiable oils, lime hardening resins and lime resistant pigments are essential in a successful cement or plaster paint. Avoid glue or casein-bound waterpaints containing alkaline carbonates or borates and on no account use linseed oil paints as a first coat. The perfect treatment consists of carefully applying two full coats of the preparatory sealer, giving 16 hours between each, then applying a body colour and finishing with a coloured cement glaze, a sand finish, imitation stone, marble finish, or plastic textured or stipple surface, colouring and decorating as may be required.

New asbestos cement sheets and raw concrete walls treated by this process will yield satisfactory results.

For aged and weathered cement surfaces wash down with clean water, proceed with one coat of preparatory sealer and then one body colour and one finishing coat.

Dr. Angus Smith's Solution.

Strictly speaking, there has never been and cannot be a Dr. Angus Smith's solution. His patent applied to the method of dipping hot iron castings, pipes, columns, ironwork, etc., in a mixture of coal tar, pitch and tallow.

The use of the mixture has been abandoned for many years, and plastic bitumens have taken its place. Where it is necessary to use cold-drying solutions the plastic bitumens are dissolved in naphtha and boiled oil and applied by spraying, brushing or dipping. They dry in 1½ to 6 hours and are cheap and durable.

Graphite Paints.

For steelwork the inert properties of silico-carbon (graphite) to attacks by moisture, gases, acids and alkalis appear to offer advantages in protection against corrosion. The electro-positive cathodic quality of carbon (best graphites range as high as 95 per cent. carbon) to iron and steel, however, accelerates corrosion and condemns the use of carbon pigments as steel primers. For second and third coats over really inhibitive pigments such as red lead, basic chromate, zinc chromate, blue lead, etc., graphites are excellent materials if mixed in proper media. Silica-graphites, although rough in texture and poor in opacity, give best results when of high purity. The carbonaceous silica graphites should not be confused with the ferro-silicates (micaceous iron ores) compounds found in Devon (England), Wales, Germany and Sweden. These latter are of special interest as they afford excellent protection to steel when carefully refined and mixed with proper water-resisting media although they are very similar in appearance to the silica graphites which are not satisfactory in contact with iron. The ferro-silicates contain as high as 95 per cent. of iron oxide chemically combined with silica, etc. These ferro-silicates are mixed with zinc and iron oxides, white leads, green and black pigments, aluminium, etc., to make a wide range of colours for the protection of steelwork against the attacks of sulphur, acids, alkalis and sea water. They are marketed under well-known brands. They weigh about 18 lbs. per gallon (against graphite 12½ lbs.), cover 70 sq. ft. per lb. (graphite 100–110 sq. ft.). In actual exposure tests of many types of carbonaceous graphite and ferro-silicate graphites the superior durability of the ferro-silicates as steel primers is very marked being only surpassed by the lead pigments. The paints are low in cost and easily applied.

Wood Preservatives and Stains.

Treatment of timber involves the use of anti-fungus and bactericidal compounds in solvents to permit of deep penetration and ease of application. Among the fungicides are coal tar, wood tar, etc., dissolved in creosote or naphtha, creosote, wood-oil varnishes, paints and enamels, carbolic acid compounds, with alkali salts, sulphur derivatives and metallic soaps containing essential oils and volatile insecticides. In recent years the use of metallic compounds, *i.e.*, copper, iron, lead, nickel, arsenic, manganese, aluminium, magnesium, etc., with creosote or oleic acids and naphthenic acids have given satisfactory results. The copper compounds are green, those of iron and manganese are brown, whilst the transparent types are made with lead, magnesium. zinc or aluminium, being dissolved in coal tar, naphtha or white spirit. They are applied by brushing, dipping or spraying. For protection against dry rot and the fungi usually found in the woodwork of buildings, the copper compounds are very effective. To prevent decay and damage by insects, *e.g.*, the death watch beetle, special sprays are prepared from essential oils, cyclo-hexanone compounds, solvents and waxes.

The use of waxes, varnishes, polishes and stains has grown tremendously during recent years. Ceresin, carnauba, japan, montan and paraffin waxes, natural resins and drying oils in solvents mixed with bitumens and asphaltums or dyes and colours provide the range of products available. They are applied by brushing, rubbing or mechanical means. Waxes are now emulsified into colloidal liquids without the use of alkaline soaps and produce glossy and hard-wearing coatings that are antiseptic, durable and efficient.

LUMINOUS PAINTS.

Compounds of calcium, zinc and sulphur are well known for their property of retaining and reflecting light rays in the dark. They are surpassed however by the rare earth compounds, *e.g.*, radio-thorium, thorium bromide, mesothorium, etc., which are used on optical instruments, watches, gun sights, binoculars and range finders, etc., etc.

They are among the most expensive paint materials known.

NOVELTY ' FINISHES.

Research work into the causes of the cracking of paint and varnish films led to the production of means of controlling or producing the cracking, crawling or rivelling at will. The results are available as ' Crackle,' ' Ripple,' ' Frosting,' ' Crystallising,' ' Mottle,' ' Leather-grain,' ' Spottle,' etc., Types of finishes which find large application on domestic hardware, stoves, heaters, fancy goods, etc. They involve the use of specially prepared compositions of oils, resins, solvents, celluloses and chemicals and are applied by spraying with baking or air drying treatment. A very wide range of colours and finishes is available for metals, wood, glass, fabric, etc. Individual methods of working produce varied effects and colourings. Air drying and stoving processes are worked.

FINISHES FOR POLISHED METALS.

Modern metal furnishing processes involve the use of coloured glazes, or enamels applied to highly polished or polishable surfaces. Special types of enamels and lacquers are available. They may be applied successfully to the plated surfaces or may be used to treat unplated surfaces, passing through the plating bath and are polished to a high gloss with the metal plating itself.

WET-ON-WET PAINTS.

For outdoor painting conditions in which rapid drying is required of paints and compositions that have to resist weathering, heat, sea water, chemical fumes and hard-wear, the ordinary types of linseed-oil and varnish paints are quite useless, for only one durable coat can be dried in 12 to 16 hours and it is insufficient to provide adequate protection against severe and prolonged service. Successful use has been made of synthetic resin enamels and treated linseed and other drying oils which gelate quickly when applied as solutions in volatile solvents after the solvents have dried off. Owing to their peculiar properties they permit of paints being applied to painted surfaces that are still tacky. Many types are available, and decorative or anticorrosive pigments can be incorporated with the most efficient of them. Application can be made by brush or spray, brushing permits of 2 or 3 coats a day and spraying 3 to 5 coats a day, the brushed coats requiring a harder surface that takes longer to ' set off.'

The final coatings are very elastic, tough and weather resistant if made from correctly treated oils, resins and pigments.

Difficulties occur however, if the medium contains free mineral acids, sulphur compounds chlorides, aluminium, soaps or lime compounds when applied to metal or wood surfaces.

LUBRICANTS AND OILS.*

GREASES FOR RAILWAY AXLES.

(1.)

Water 1 gallon; palm oil, 6 lbs.; clean tallow, 3 lbs.; common soda, ½ lb.

(2.)

Tallow, 8 lbs.; palm oil, 10 lbs. Heat to 212° F., and well stir.

ANTIFRICTION GREASE.

(1.)

Tallow, 100 lbs.; palm oil, 70 lbs. Boil together, and when cooled to 80° F. strain through sieve and mix with 28 lbs. common soda and 1½ gallon of water.

(2.)

Blacklead, 1 part; lard, 4 parts.

*See also Section XX, Part II. (Vol. I.).

Rosin-Oil Soap.

90 lbs. powdered slaked lime, stirred into 100 lbs. rosin oil. Heat the mixture, constantly stirring it well until a uniform paste of the consistence of syrup is obtained. This rosin oil is a component of all the patent wagon greases.

Blue Patent Grease.

2 lbs. powdered slaked lime, heated in 550 lbs. of crude resin oil for 1 hour, and then allowed to cool. Skim the oil, and stir in 10 to 12 lbs. of rosin-oil soap, until the compound is of a butter consistency and of a blue colour.

Yellow Patent Grease.

1 part turpentine, 20 parts caustic lye. Add to 350 parts of blue grease.

Black Patent Grease.

2 parts lampblack, 110 parts blue grease.

Patent Palm-Oil Wagon Grease.

Melt 10 lbs. rosin-oil soap in 10 lbs. palm oil; add 550 lbs. rosin oil, with as much rosin-oil soap as will give the whole the consistence of butter; finally, add 7½ to 10 lbs. of caustic soda lye.

Adhesive Grease for Machine Belts.

Lubricate the belts with fish oil to which 10 per cent. of tallow has been added. This will make them flexible, and augment their friction on the pulleys.

Grease for Waterproofing Leather.

Oleic acid, 24 parts; crude stearic acid, 6 parts; ammoniacal soap, 18 parts; extract of tannin, 6 parts; water, 24 parts. Melt the oleic acid together with the stearic acid; then add gradually the ammoniacal soap, the extract of tannin, and finally the water. The ammoniacal soap is obtained by adding to heated oleic acid caustic ammonia until, after continued stirring, the odour of ammonia remains apparent and the whole congeals to a jelly-like mass.

Cooling Compound for Hot Bearings.

(1.)

Mercurial ointment mixed with black cylinder oil and applied every quarter of an hour, or as often as expedient. The following is also recommended as a good cooling compound for heavy bearings:—Tallow, 2 lbs.; plumbago, 6 ozs.; sugar of lead, 4 ozs. Melt the tallow with gentle heat and add the other ingredients, stirring until cold. For lubricating gearing, wooden cogs, etc., nothing better need be used than a thin mixture of soft soap and black lead.

(2.)

For cooling a hot bearing Professor Lecocq, of the Charleroi Higher Industrial School, recommends that the oil usually employed for lubrication be dissolved in an equal quantity of petroleum spirit, the evaporation of which latter will, he says, afford the cooling desired.

Watchmaker's Oil.

Expose the best olive oil to a temperature a few degrees below the freezing point, which will cause all foreign substances to separate. Pour off carefully the supernatant clear oil, and filter through a cup of linden wood or pith of elder wood. By this process an oil is obtained which will remain liquid for several years, and does not attack the delicate machinery.

Neat's-foot oil treated in the above manner furnishes a less useful oil, since it loses much fatty matter by exposure to cold.

A very useful oil is obtained by dissolving 1 part of pure neat's-foot oil in 3 of pure benzine. Allow the compound to remain for several days in a closed vessel; then filter, and expose the solution to a temperature of 40° F., at which it is again filtered, and the benzine distilled off. The oil should be kept in small, dark vials protected from the air.

A very fine lubricant for clocks and watches is, according to Artemus, obtained by mixing 2 parts of solar oil with 1 of rape-seed oil.

To Test the Fitness of Oils for Lubricating Watches and Clocks.

Pour a drop of the oil to be tested upon different metal plates, as iron, brass, tin, lead, etc.; keep them in a place free from dust, and examine the drops during 8 to 14 days in regard to their liquidity. Oil remaining liquid after the lapse of this time can be safely used.

VISCOSITY OF VARIOUS STANDARD OILS.

Description.	Viscosity.	
	At 70° F.	At 120° F.
Sperm oil	100	45
Whale oil	190	70
Olive oil	213	75
Lard oil	225	78
Neatsfoot oil	247	80
Rape-seed oil	250	88
Axle oil	600	120
Valve oil	—	550
Cylinder oil	—	700

In the above table sperm oil is taken as the standard for viscosity at 70° F.

The viscosity of thick oils can be greatly reduced by adding 8 per cent. of naphthalen to the oil.

An objectionable characteristic in an oil is its tendency to become resinous with use, due to the oil undergoing the process of oxidation. This change in the oil indicates, to some extent, the degree of refining process the oil has undergone. A simple test can be made in the following way :—Place a small quantity of oil in a glass beaker and put in a nearly equal amount of nitric acid, Should the oil have no tendency to gum, the acid and oil will combine and get very thick, while should there be any objectionable characteristic the oil will remain thin.

SECTION XLIII

PATENTS, DESIGNS, AND TRADE MARKS

(Revised by G. W. Tookey, Barrister-at-Law.)

(Pp. 1001–1013)

SECTION XLIII

PATENTS, DESIGNS, AND TRADE MARKS.

(Revised by G. W. Tookey, Barrister-at-Law.)

[The references at the ends of the paragraphs are to the relevant sections of the Patents and Designs Acts, 1907–1946, and the Trade Marks Act, 1938.]

PATENTS.

(Patents and Designs Acts, 1907–1946.)

Acceptance.—Acceptance takes place after an application is in order which normally must be within eighteen months of the date of the application for the patent. This period for putting an application in order may be extended up to three months on payment of fees and may be further extended during the period in which an Appeal is open or pending. An application is deemed to be in order when the complete specification has been finally left after the Applicant has complied with all requirements. (8a.)

The Comptroller may postpone acceptance to a date not later than twenty-one months from the date of application if requested by the applicant.

Acceptance is advertised in the Official Journal (Patents) and specifications and samples (if any) are open to public inspection. (9.)

After acceptance the applicant has full rights under the patent but may not commence proceedings for infringement until the patent is actually sealed. (10.)

Addition, Patent of.—An applicant or patentee may apply for further patents in respect of improvements or modifications and request their grant for the unexpired term of the main patent. In such cases Patents of Addition are granted and no renewal fees are required in respect thereof. Independent patents can be converted into Patents of Addition and *vice versa.* (19.)

Amendment of Specification after grant or acceptance.—A Complete Specification and drawings may be amended by way of disclaimer correction or explanation on application to the Comptroller if good reasons are given. Opposition may be entered. An appeal lies to the Appeal Tribunal, if the patent has not yet been granted, and after grant an appeal lies to the Court.

No amendment is allowed which will make the specification claim an invention substantially larger than or different from that claimed before amendment.

If infringement or revocation proceedings are pending an application for leave to amend must be made to the Court and not to the Comptroller. (21, 22.)

Damages for infringement before amendment cannot be obtained unless the patentee establishes that his original claim was framed in good faith and with reasonable skill and knowledge. (23.)

Anticipation.—A patent is not anticipated by reason only of its publication in the United Kingdom in a specification relating to a patent over fifty years old, whether a British or foreign specification, or in any official abridgment or extract from such a specification, or in a provisional specification not followed by a complete specification.

Prior publication does not invalidate a patent if the patentee can prove that the publication was made without the knowledge and consent of the true inventor and that the published matter was obtained from the true inventor, and that the inventor applied for a patent as soon as possible after hearing of the publication. (41.)

Appeal Tribunal.—A High Court Judge is appointed as the Appeal Tribunal to hear appeals from the Comptroller on matters arising in the course of applications. (92a.)

Hearings are in private and Patent Agents have a right of audience.

Application for Patent.—An application (£1) can be made by any person whether a British subject or not claiming to be the true and first inventor, either alone or jointly with others, who need not be joint inventors. The application must be accompanied by either a provisional or complete specification. (1.)

Certificate of Validity.—In an infringement action the Court may certify that the validity of any claim came in question, and in any subsequent action, if successful, the plaintiff may receive full solicitor and client costs in respect of that claim. (35.)

Chemical Processes, Foods and Medicines.—In the case of inventions relating to substances prepared by chemical processes or intended for food or medicine, the specification must not include claims for the substance itself except when prepared by the methods or processes of manufacture particularly described and ascertained in the specification or by their obvious chemical equivalents. In the case of foods and medicines, a mere mixture simply aggregating the known properties of the ingredients is not patentable. (38a (1).)

In an infringement action relating to a patent for the production of a new substance, in the absence of proof to the contrary, any substance of the same chemical composition is deemed to have been produced by the patented process. (38a (2).)

The Comptroller will (unless he sees good reason to the contrary) grant compulsory licences in respect of patents for inventions for the production or preparation of food or medicine on terms which allow the public the product at the lowest possible price consistent with giving to the inventor due reward for the research leading to the invention. An appeal lies to the Court. (38a (3).)

Cognate Inventions.—Provisional specifications of the same applicant for inventions which are cognate or modifications one of the other may be combined into one complete specification on which a single patent is granted.

The patent bears the date of the earliest provisional specification but in considering validity and other questions under the Acts regard may be had to the individual dates of the provisional applications corresponding with the various claims of the complete specification. (16.)

Convention Applications.—Any person who has applied for protection for an invention in a Convention country is entitled to a U.K. patent having the same date as the date of application in the Convention country. Application must be made in U.K. within twelve months from date of application in the Convention country. (91.)

Convention countries are those declared to be such by Orders in Council. (91a.)

The U.K. application must be accompanied by a complete specification which will become open to inspection, together with the filed copy of the original application, at the expiration of eighteen months from the priority date claimed, whether or not the specification has by then been accepted. (91.)

Court.—Infringement and revocation proceedings and references to the Court under s. 29 are taken in the High Court (usually the Chancery Division) and may be heard by any judge.

References to ' the Court ' in sections of the Patent Acts dealing with appeals from the Comptroller and applications for extension of patents are to the special ' patent ' judge appointed by the Lord Chancellor. The special judge is usually different from the judge constituting the ' Appeal Tribunal.' Patent agents have a right of audience before the Appeal Tribunal but not before the Court.

Crown Rights.—Any Government Department or their authorised agents or contractors may make use of an invention for the services of the Crown on terms agreed with the patentee and approved by the Treasury, or settled by the Court which may appoint an arbitrator. (29 (1).) The Royal Commission on Awards to Inventors is specially empowered to deal with disputes between patentees and Government departments on this matter, provided both parties consent.

During the war period (at present extended till December 10, 1950, by Emergency Laws (Miscellaneous Provisions) Act, 1947), Governmental powers are extended to include the use of inventions for the wide purposes set out in Supplies and Services (Transitional Powers) Act, 1945.

The terms of any agreement or licence between the patentee and any other persons are inoperative so far as concerns the making, use or exercise of the invention for the service of the Crown. (29 (1).)

If an invention covered by a patent was recorded in a document or tried by a Government Department (not having been communicated by the patentee or applicant), before the date of the application for the patent, the invention can at any time be used by any Government Department or authorised agent or contractor without payment to the patentee. (29 (1.))

Crown rights cover the sale of articles no longer required for Crown service and also the sale of articles forfeited under the Customs and Excise laws. (29 (3) and (4).)

Date of Application.—The date of application is either the date of filing of an application or any date to which it may be ante- or post-dated (4).

Date of Patent.—All patents are normally dated as of the date of application, but no proceedings can be taken in respect of an infringement committed before acceptance of the complete specification (13), and proceedings cannot actually be instituted until the date of sealing of the Patent. (10.)

For cases in which patents are given a priority date see under ' Convention Applications ' and ' Fraudulent Applications.'

Effect, Extent and Form of Patent.—Patents are effective throughout the United Kingdom and the Isle of Man. Every patent shall be for one invention only but the specification may contain

more than one claim. No objection to a patent on the ground that it has been granted for more than one invention can be raised after grant. The United Kingdom includes Northern Ireland. (14.)

Employee.—Application for patents for inventions made by an employee must include the name of the employee as inventor, but the employer may be entitled to the whole beneficial interest in the patent depending on the terms of the employment. If the employer is so entitled, the employee will be required to assign his interest in the patent when granted.

Enemy Patents.—An application for a patent based on an invention made in Germany or Japan or by a German or Japanese national in any enemy territory between September 3, 1938, and December 31, 1945, will be refused. (P. & D. Act, 1946). As to revocation of such patents, if granted, see ' Revocation.'

Most German-owned U.K. patents granted before the war will have lapsed for non-payment of renewal fees, but some such patents will have been kept in force by British licensees whose interests are protected under emergency legislation and by international agreement.

Examination of Applications.—If the Examiner reports that the application is not properly prepared the application may be rejected until suitably amended and the application may be post-dated to the date of filing of a satisfactory amendment. On request by the applicant a complete specification may be treated as a provisional specification, to be followed by a complete specification in the usual manner. The applicant may before acceptance obtain post-dating of his application for a period up to six months, on payment of a fee. Notice of acceptance of an application is given to the applicant. Appeal from decision of Comptroller on these matters lies to the Appeal Tribunal. (3.)

Examination of Complete Specification.—If a complete specification is filed after a provisional and the Examiner reports that it is not properly prepared, the Comptroller may refuse to accept the specification until suitable amendments have been made. If the examiner reports that the invention described in the complete specification is not the same as that described in the provisional specification, the Comptroller may :

(*a*) refuse to accept the complete specification until satisfactorily amended ;
(*b*) (with consent of the applicant) cancel provisional specification and proceed with application on the basis of the date of leaving of the complete specification.

Any invention in a complete specification not found in the provisional specification may be removed and embodied in a separate new application which can be ante-dated to the date of leaving of the original complete specification.

Appeal lies to the Appeal Tribunal (6). See also ' Search.'

Examiner's Reports. Examiner's reports shall not be open to public inspection or production in legal proceedings except by direction of the Court. However, on payment of a fee the Comptroller may disclose references to documents and numbers of patent specifications cited as a result of the novelty search, in respect of complete specifications accepted or published. (68.)

Exhibition.—The exhibition and use of an invention at an industrial or international exhibition certified by the Board of Trade, or the use of the invention during the exhibition by any person elsewhere without the consent of the inventor, or the reading of a paper before a learned society or its publication in the society's transactions, does not invalidate a patent subsequently applied for, provided that notice is given to the Comptroller of intention to exhibit the invention or read the paper, and the application for a patent is made within six months from the opening of the exhibition or the reading of the paper. (45.)

Extension of Term on ground of inadequate remuneration.—Application for extension of the term of a patent on the ground of inadequate remuneration may be made by Petition to the High Court. If the Court considers that a patentee has been inadequately remunerated, having regard to the nature and merits of the invention in relation to the public, to the profits made by the patentee as such, and to all the circumstances of the case, the term of the patent may be extended by five years or in exceptional cases ten years, or the grant of a new patent may be ordered for a specific term and subject to any restrictions or conditions thought fit by the Court (18.) There is no appeal from the Court's decision.

Extension of Term on ground of War loss.—If a patentee not being an enemy subject or enemy controlled company has suffered loss or damage (including loss of opportunity of dealing in or developing his invention due to his being engaged in work of national importance connected with hostilities) an application may be made to the Court or at the option of the Patentee to the Comptroller for an extension of term of the patent on this ground alone. The aggregate extension under one or more applications shall not exceed ten years. A simple procedure is provided for applications made to the Comptroller but cases raising important issues may be referred by the Comptroller to the Court.

Appeal lies from decisions of the Comptroller to the Appeal Tribunal. There is no appeal from the decisions of the Court or the Appeal Tribunal. (18.)

Foods.—See ' Chemical Processes, etc.'

Fraudulent Applications.—A patent granted to the true and first inventor is not invalidated by an application in fraud of his rights or by use or publication of the invention after provisional

protection has been fraudulently obtained. If a patent is wholly or partially refused on opposition or revoked on the ground of fraud a patent for the whole or part of the invention may be granted to the true and first inventor in lieu of and bearing the same date as the refused application or revoked patent. (15.)

Grant of Patent.—A patent will be granted to an applicant, or to several applicants jointly, or to an assignee, on payment of the sealing fee. (12.) If lost or destroyed a duplicate patent may be issued. (44.)

Illegal Conditions of Sale and Licence of Patented Articles.—In contracts relating to the sale or lease of or licence to use or work any article or process protected by a patent conditions prohibiting the use of articles (whether patented or not) or patented processes supplied or owned by third parties or requiring the acquisition from the patentee or his nominee of unpatented articles are illegal unless the purchaser, lessee or licensee was offered at the time of the contract an alternative contract on reasonable terms but without the above conditions and the contract itself allows for three months' notice of termination on payment of compensation.

The foregoing provision does not affect conditions prohibiting persons from selling goods other than those of a particular person or reserving to the licensor the right to supply new parts for putting or keeping a patented article in repair.

The continuing existence of an illegal contract as above is a bar to obtaining relief in an infringement action. (38.)

Infringement Action.—In an infringement action a plaintiff may obtain an injunction, damages, delivery up of infringing articles and costs.

A defendant may deny that he has infringed the monopoly claimed in the patent specification and may attack the validity of the patent, wholly or in part. He may further by way of counterclaim seek revocation of the patent on the ground of invalidity. (32.)

The insertion of illegal conditions in licences or contracts is available as a defence while contract is in force. (38.) See 'Illegal conditions of Sale and Licence.'

If some claims are found valid and others invalid, the patentee may obtain limited relief and may be put on terms as to amendment of his patent. An order for revocation may be stayed to allow the patentee to amend on suitable terms. (32a.)

Infringement, Innocent.—No damages for infringement can be recovered from a defendant who proves he was not aware nor had reasonable means of making himself aware of the existence of the patent; the mere marking of articles 'patent,' 'patented,' or with other equivalent wording without the number of the patent, is not sufficient notice of the existence of the patent. Innocence, however, does not affect proceedings for an injunction. (33.)

Inventor.—An application for a patent other than a Convention Application must be made by the inventor himself either alone or jointly with other persons or by the legal representative of a deceased inventor. Failure to do so is a ground for revocation. (25, 43.)

The inventor of the whole or a substantial part of the invention has a right to be mentioned as such and may apply to the Comptroller to enforce his rights. The mention of an inventor as such does not confer or derogate from any rights under the patent. (11a.)

Joint Applicants.—Where a joint applicant has died, a patent may with the consent of his personal representative be granted to the survivor or survivors of the joint applicants.

Where an applicant (*e.g.* an employee) has agreed in writing to assign his interest in a patent when sealed (*e.g.* to his employers) the patent may be granted direct to the assignee. A similar provision applies where one joint applicant has assigned his interest, so that a patent may be granted to the assignee jointly with the other applicant or his assignee.

In case of disputes between joint applicants or their assignees, the Comptroller may allow one or more to proceed alone and may grant a patent to him or them subject to all parties being heard.

An appeal lies to the Appeal Tribunal. (12.)

Joint Patentees.—Where a patent is granted to several persons jointly they shall be treated legally as if they were joint tenants, but subject to any contract to the contrary each may use the invention for his own profit without accounting to the others but can only grant licences with their consent. On death the beneficial interest of a joint tenant passes to his personal representatives.

If joint patentees disagree the Comptroller may give directions as to the sale, lease, or licence of the patent, or the use or exploitation of the rights, and in default of compliance the Comptroller may empower any person to execute the requisite documents to give effect to his directions.

Appeal lies to the Court. (37.)

Licences.—Licences may be exclusive or non-exclusive. The rules of contract generally apply, but certain conditions are illegal (see 'Illegal conditions, etc.'). Furthermore a licence may be determined by either party on three months' notice after all the patents in force at the date of the licence have ceased to be in force, notwithstanding anything in the licence to the contrary. (38.) This is intended as a check on the use of the patent monopoly as a means of extracting royalties for unreasonable periods. Limited licences under patents may be granted to control price of resale, etc., but the terms of such licences must be brought to the notice of purchasers at the time of purchase.

Licences of Right.—Patents may be indorsed 'Licences of Right' with the following effect:—

1. Any person can claim a licence upon terms which, if not agreed, may be settled by the Comptroller.
2. Such a licence may exclude the importation from abroad of any goods covered by the patent.
3. If the patentee will not take action against infringers the licensee may take action in his own name. In an infringement action the defendant may take a 'Licence of Right' to avoid an injunction, with limitation of damages if his infringement is not by importation.
4. A patent indorsed 'Licences of Right' is subject to one-half of the normal renewal fees.

Applications for indorsement may be opposed and must not be precluded by contract. The indorsement of main patents extends to patents of addition thereon and *vice versa.*

An indorsement may be cancelled on request of patentee, but such applications are open to opposition.

An appeal from the Comptroller lies to the Court. (24.)

Manufacture.—A mere scheme or plan is not a 'manufacture' for which a patent may be granted.

Marking.—No marking necessary before acceptance but subsequently, see 'Infringement, Innocent.'

Medicines.—See 'Chemical Processes, etc.'

Opposition to Grant of Patent.—Within two months from date of advertisement of acceptance or within one month's extension if applied for within the said two months, notice of opposition by anyone having an interest may be filed at the Patent Office, on one or more of the following grounds only :—

(*a*) Fraud, *i.e.* whole or part of invention obtained from opponent.

(*b*) Prior publication in a U.K. patent specification dated within fifty years of the date of the application, or prior publication (in such a way as to make the invention available to the public) in any other document published in the U.K. (other than a patent specification over 50 years old).

(*bb*) Prior claiming in a U.K. specification not published in time to count as a prior publication.

(*c*) Insufficient or unfair description.

(*d*) Disconformity between provisional and complete specifications, the opponent having applied for a patent for the disconforming matter, or such matter having been published.

(*e*) In the case of applications under the Convention disconformity between the complete specification and the basic foreign specification with publication or patent application by opponent as under (*d*).

(*f*) Invention made in Germany or Japan between September 3, 1938, and December 31, 1945, or made between such dates by a German or Japanese National in any territory which was then enemy territory.

Appeal lies to the Appeal Tribunal. (11.)

Any person who would have been entitled to oppose the grant of a patent may within twelve months of sealing apply to the Comptroller for revocation on any of the above grounds. Such an application (often referred to as 'belated opposition') cannot be made if court proceedings on the patent are pending. Appeals in belated oppositions are to the Court, not to the Appeal Tribunal. (26.)

Patentee.—'Patentee' means the grantee or the subsequent registered proprietor of the patent. (93.)

Provisional Protection.—Inventions may safely be used and published between the dates of 'application' and 'acceptance' such period of protection being called 'provisional protection.' (4.)

Register of Patents.—The Register of Patents is kept at the Patent Office and contains entries of all matters pertaining to the validity and proprietorship of patents and all proceedings in relation thereto. Register is available for public inspection and certified copies of entries are obtainable. Copies of deeds, licences and any other documents entered in the Register must be supplied for filing in the Patent Office. (28) and (67.)

Restoration of Lapsed Patents.—Patents lapsed through non-payment of renewal fees may be restored by the Comptroller if he is satisfied that the omission to renew was unintentional and no undue delay occurred in applying for restoration. The Comptroller will impose terms to protect those who have started working the patent in the interim period. Opposition may be entered. The fee on application to restore is £20.

An appeal lies to the Court. (20.)

Revocation of Patent.—Revocation of a patent may be obtained, on petition to the Court, or by way of counterclaim in an infringement action, on any of the following grounds :—

(*a*) Invention already validly patented.

(*b*) Subject to special provisions as to convention applications the true and first inventor is not a party to the application.

(*c*) Patent obtained in fraud of the rights of the person seeking revocation.

(*d*) Invention not a 'manner of new manufacture.'

(*e*) Invention not new.
(*f*) Invention obvious and does not involve invention.
(*g*) Invention not useful.
(*h*) Insufficient description in the complete specification of the nature of the invention and how it is to be performed.
(*i*) Scope of the monopoly not sufficiently and clearly ascertained.
(*j*) The best method known to the applicant of carrying the invention into practice not described in the complete specification.
(*k*) Patent obtained on a false suggestion.
(*l*) Disconformity between the provisional and complete specification, the disconforming matter not being new or not invented by the applicant; or in the case of Convention applications disconformity between the complete specification and the basic foreign specification.
(*m*) Primary or intended use of the invention contrary to law.
(*n*) Patentee has contravened or not complied with the conditions of the patent.
(*o*) Invention secretly worked before date of patent on a commercial scale in the United Kingdom by the patentee or others not being a Government Department or authorised contractors therefor.
(*oo*) In a war period secret working by a Government Department or their agents before date of patent, such working not being by reason of a disclosure by the applicant.
(*p*) That in the case of substances prepared or produced by chemical processes or intended for food or medicine the specification contravenes Section 38a of the Act.
(*q*) Invention made in Germany or Japan between September 3, 1938, and December 31, 1945, or made between such dates by a German or Japanese national in any territory which was then enemy territory.

Any of the above grounds of revocation are available as a defence in an infringement action. (25.)

As to an application to revoke by way of 'belated opposition' see under 'Opposition.'

Royal Arms.—The grant of a patent does not entitle the patentee to use the Royal Arms or to place them on the patented article. Penalty £20. (90.)

Sealing of Patent.—Normally patents must be sealed (£1) not later than twenty-one months from date of application, but if any extension of time has been allowed for filing or accepting the complete specification, a period of twenty-five months is allowed for sealing.

In the case of opposition or appeal the period allowed for sealing is determined by the Comptroller or the Appeal Tribunal.

When a patent is granted to legal representative of a deceased applicant, it may be sealed at any time within twelve months of the death or later if allowed by Comptroller.

Sealing may be delayed for periods up to six months upon application and payment of extension fees and further extensions may be allowed as may be necessary to avoid hardship which might otherwise arise in connection with applications in countries abroad.

Search—Novelty.—The Examiner investigates whether the invention claimed in the complete specification has been wholly or in part claimed or described in any complete specification (or its corresponding provisional specification) left pursuant to an application for a patent in the United Kingdom dated within fifty years prior to the priority date or date of filing of the application. If invention has been wholly or in part claimed or described as aforesaid, applicant is allowed to amend his specification and the amended specification is examined in the same manner as the original specification. If the Comptroller is satisfied that no objection exists, he accepts the specification in the absence of any other lawful objection. If the Comptroller is not so satisfied he determines whether a reference to any particular prior specification ought to be made by way of notice to the public.

If the Comptroller is satisfied that the invention claimed has been wholly and specifically claimed or described in any prior specification he may, instead of inserting references, refuse to grant a patent.

If within the knowledge of the Comptroller the invention claimed has been made available to the public by publication in the United Kingdom in any document prior to the date of the application or its priority date (other than a specification more than fifty years old), the above provisions apply.

Appeal lies to the Appeal Tribunal. (7.)

The Examiner also investigates specifications relating to applications of prior date but published after the application date or priority date of the application, to ascertain whether the invention claimed has been wholly or in part claimed in any such prior specifications. In the case of whole or partial prior claiming, complete specification may be amended, or if not satisfactorily amended Comptroller may insert a reference to other specifications by way of notice to the public.

Appeal lies to the Appeal Tribunal.

Novelty investigations give no guarantee of validity of patent and Board of Trade accept no liability in respect of the investigations and reports thereon. (8.) See also 'Examiners Reports.'

Secret Patents, etc.—The inventor of any improvement in instruments or munitions of war may assign the invention and ultimate patent to the Secretary of State for War, for Air or the Admiralty, with or without valuable consideration.

When such an assignment has been made, the Secretary of State or the Admiralty can issue a certificate authorising the Comptroller to treat the application and all relevant papers as secret. (30.)

Under Emergency Legislation which will continue in force until December 10, 1950, various Ministers have powers to control applications for patents if such course is in the public interest.

Specifications.—Provisional specification must describe the nature of the invention. Complete specification must describe and define the invention in detail and the manner in which it can be carried into practice. Drawings may be required as part of the specification. Complete specifications must end with a clear statement of the invention claimed. The 'claims' of the complete specification are important because they define the ambit of the monopoly provided by the patent. In the case of chemical inventions samples may be required or may be supplied. (2.)

Complete specifications (£4) if not filed on application must be filed within twelve months from date of filing. One month's extension of this period is obtainable on payment of a fee. If a complete specification is not filed within thirteen months the application is regarded as abandoned. (5.)

Term of Patent.—The normal term of a patent granted on and after August 1, 1938, begins on the date of the patent and ends at the expiration of sixteen years from the date on which the specification accepted as complete specification is treated by the Comptroller as having been first left.

Both these dates are entered upon the Register of Patents. Continuance of the patent is, however, subject to the payment of the prescribed renewal fees which commence at the end of the fourth year from the date of the patent (not date of sealing or date of filing complete specification). Up to three months extension of time for payment can be obtained on payment of a fee (17 and Rules). The term of patents granted before August 1, 1938, is sixteen years from the date of the patent.

Threats.—If anyone by circulars, advertisements or otherwise threatens anyone with an action for infringement of patent or other like proceedings, then any person aggrieved thereby may bring an action to restrain such threats and recover damages, whether the person making the threats is or is not interested in a patent or patent application, unless the person making the threats can prove they are justified, *i.e.* the patent contains valid claims which are or would be infringed, or rights arising from the acceptance of a complete specification would be infringed in respect of a claim not capable of being successfully opposed. The defendant in such proceedings may seek by counterclaim the relief to which he would be entitled in an infringement action.

Vessels, Aircraft, etc., use of Inventions on.—A patent is not infringed by its use in a vessel, aircraft or land vehicle belonging to a Convention Country if it is used in the body of the vessel, etc., or in the machinery, tackle, etc., and if the vessel, etc., comes only temporarily or accidentally into Great Britain or its territorial waters and (in the case of a vessel) the invention is used exclusively for the actual needs of the vessel. (48.)

The Air Navigation Act, 1947, provides for wider protection for aircraft in the above matters, covering for example the storage in U.K. of spare parts and equipment for foreign aircraft.

Working (Definition).—'Working on a commercial scale' means the manufacture of the article or carrying on of the process described and claimed by a definite and substantial establishment or organisation and on an adequate or reasonable scale. (93.)

Working (Abuse of Monopoly).—At any time after three years from sealing any interested party may apply to the Comptroller for relief on the ground that the patent monopoly is being abused in any of the following circumstances :—

1. The invention is not being worked in the United Kingdom on a commercial scale and there is no satisfactory reason for such non-working.
2. The working in the United Kingdom is being hindered by importation from abroad of the patented article by the patentee or with his assent or by infringers against whom the patentee has not taken action.
3. If the demand in the United Kingdom is not being met to an adequate extent and on reasonable terms.
4. If because the patentee will not grant licences on reasonable terms trade or industry is being prejudiced, it being in the public interest for licences to be granted.
5. If any trade or industry is being prejudiced by conditions attached by the patentee to purchase, hire, licence, or use of a patented article or to the working of a patented process.
6. If the patent relates to a process involving the use of materials not protected by the patent and is being used by the patentee so as unfairly to prejudice the manufacture, use or sale of such materials in the United Kingdom.

The Comptroller may take action as follows :—

1. He may endorse patent 'Licences of Right.'
2. He may grant a licence to the applicant on suitable terms.
3. If he is satisfied that lack of capital is preventing exploitation and the patentee does not undertake to find such capital, he may grant an exclusive licence to the applicant on suitable terms. In granting such an exclusive licence the Comptroller will usually prefer an existing licensee to other persons.

4. If he thinks the manufacture use or sale of unpatented materials for use in carrying out the invention contained in the patent is being prejudiced, he may grant licences to the applicant and to any of the applicant's customers on such terms as he may think fit.

5. He may make no order if he considers it just so to do.

6. As a last resort, and subject to certain conditions he may revoke the patent.

DESIGNS.

Patents and Designs Acts, 1907–1946.

Additional Registrations.—A design already registered may be subsequently registered by the proprietor in other classes such registrations expiring with the original registration.
Similarly a design which differs from a previously registered design of the proprietor only in unimportant respects may be registered in the same class expiring with the original registration. (50.)

Anticipation.—A design registration is not invalidated by prior confidential disclosure of the design, or if the design is disclosed in breach of such confidence, or by the acceptance of a first and confidential order for a new textile design intended for registration. (55.)

Application for Registration (10*s*.).—Upon the application of a person claiming to be the proprietor the Comptroller may register any new or original design not previously published in the United Kingdom. The same design may be registered in more than one class. If the Comptroller refuses registration, an Appeal may be made to the Appeal Tribunal. Applications not completed within the prescribed time through neglect on the part of the applicant may be regarded as abandoned. Designs are registered as of the date of application for registration. (49.)

Article.—'Article' (as respects designs) means any article of manufacture and any substance wholly or partly artificial or natural. (93.)

Cancellation of Registration.—Any person may apply to the Comptroller for cancellation of a registration on the ground that it was published in the United Kingdom prior to the date of application. On such an application the only question is whether the design has been published; the question of its novelty or originality does not arise. See also 'Validity.'
Appeal lies from the Comptroller to the Appeal Tribunal, and the Comptroller may refer application to the Appeal Tribunal for trial. (58.)

Certificate of Registration.—Certificates of registration are issued and duplicates may be obtained in the event of loss. (51.)

Certificates of Validity.—Provisions similar to those for patents. (61.)

Classes of Designs.—For the purposes of registration articles are classified in fifteen classes based partly on the materials of which the article is composed, *e.g.* metal, wood, glass, etc., and partly on the nature of the article, *e.g.* books, shoes, carpets, etc. Registration in any class covers the application of the design to any article in the same class. Correspondingly novelty and originality must be judged against designs previously applied to other articles in the same class.

Compulsory Licence.—Interested parties may apply for a compulsory licence on grounds that the design is industrially used outside the United Kingdom and not to a reasonable extent within the United Kingdom. The Comptroller may make any order at his discretion. Appeal lies to Appeal Tribunal and the Comptroller may refer application to the Appeal Tribunal for trial. (58.)

Convention Applications.—Priority of date may be obtained for applications made under the International Convention within six months from the application for protection in the convention country. (91.)

Copyright in Designs.—'Copyright' in designs is the exclusive right to apply a design to an article in any class in which the design is registered. (93). The acts of piracy of design copyright in respect of which proceedings may be taken are, however, limited, see 'Infringement.' Design copyright is to be distinguished from artistic copyright under the Copyright Act, 1911. There may, however, be some overlapping of the two forms of protection, and reference should be made to fuller treatises on the subject for further information.

Crown Rights.—The provisions as regards patents also apply to registered designs. (29, 58a.)

Design.—'Design' means only the features of shape, configuration, pattern or ornament applied to any article by any industrial process or means, whether manual, mechanical, or chemical, separate or combined, which in the finished article appeal to and are judged solely by the eye; but does not include any mode or principle of construction or anything which is substance is a mere mechanical device. (93.)

Duration of Design.—Registration of a design gives copyright for five years from the date of registration. This may be extended by renewal for two successive periods of five years. (Fees £2 and £5 respectively.) (53.)

Exhibitions.—Provisions similar to those for patents apply to designs. (59.)

Infringement.—It is an infringement to apply a registered design or any fraudulent or obvious imitation thereof for the purpose of sale to any article in any class of goods in which the design is registered, except with the licence or consent of the registered proprietor or to do anything with a view to enable the design to be so applied. It is also an infringement to publish or expose for sale articles known to have a design or a fraudulent or obvious imitation thereof applied thereto without the consent of the proprietor. The proprietor may bring an action for statutory penalties (not exceeding £100) or for an injunction and damages. (60.)

Inspection of Registered Designs.—Registered designs are open to inspection by the public in most classes as soon as registration has been effected but in classes 7 and 9 (paper hangings and lace) and in classes 13, 14 and 15 (textile goods) the right to inspect is withheld for periods of two and three years respectively. Any design cited as an anticipation of a new application may be inspected by the Applicant. Copies may be obtained when design is open to inspection. (56) and Designs Rule 67.

Marking.—Before any goods are marketed under a registered design each article must, except in the case of certain textiles, be marked REGISTERED, REGD. or RD. with the number of the relevant registered design. Failing this a proprietor cannot usually recover damages for infringement of the design unless he can prove that he took all the necessary steps to ensure the marking of the article or unless he shows that the infringement took place after the infringer had been notified of the existence of the design registration. (54) and Design Rule 64.

Mechanical Devices.—A design registration is not a 'little patent' and mere mechanical devices and principles of construction cannot be protected by such registration. (93.)

Proprietor of a New or Original Design.—'Proprietor' of a new or original design means any person for whom the author executes the work for good consideration, or any person who has acquired the design or the right to apply it to any article. In any other case the proprietor means the author. (93.)

Register.—Particulars of all designs, assignments, and documents relating thereto are kept in a Register which is open to inspection on payment of a fee. (52.)

Threats.—Provisions similar to those for patents. (61.)

Validity.—The validity of a design registration may be challenged by way of counterclaim in an infringement action. A design may also be removed from the register upon application to the Court by originating motion.

GENERAL.

Applications abandoned.—Documents or samples relating to patent applications (other than Convention applications) abandoned before publication and abandoned design applications are not open to public inspection. (69.) This rule does not apply to certain applications made by enemies during the war.

Assignments, Registration of.—All assignments relating to patents and registered designs must be entered on the Register and copies of the documen ts must be supplied. After six months from execution the fee for registration becomes increased from £1 to £10. (71) and Design Rules 1st Schedule.

Clerical Errors, Correction of.—Clerical errors in patent specifications or design application s may be corrected if they do not materially alter the meaning or scope of the document which is corrected. (70.)

Costs, Award of, by Comptroller.—The Comptroller can award costs in any proceedings before him under the Act, and his order may be made a rule of Court. In the case of opponents not residing or carrying on business in the United Kingdom the Comptroller may require security for costs. (73a).

Excluded Days.—Where the last day for carrying out an act required by law falls on a Saturday, Sunday or public holiday, the act may be done on the next following day. (82.)

False Marking.—Anyone falsely representing an article sold to be patented, or falsely representing any design applied to any article sold by him to be registered, is liable to fines not exceeding £5 for every offence. Any person marking an article as 'registered' after expiry of the copyright in a registered design is liable to a fine not exceeding £5. (89.)

Frivolous Applications and Illegal Patents or Designs.—The Comptroller may refuse a patent for an invention so obviously contrary to well-established natural laws that the application is frivolous, or to grant a patent or register a design the use of which would be contrary to law or morality. A patent may be granted with a disclaimer as to illegal use of the invention. Appeal lies to the Appeal Tribunal. (75.)

TRADE MARKS.

(Trade Marks Act, 1938.)

Alteration of Mark.—The registered proprietor may amend a trade mark in any manner not substantially affecting its identity. An appeal lies against the refusal, or terms imposed by Registrar, to the Board of Trade or to the Court. (35.)

Amendment of Application.—Errors may be corrected or amendments made at any time before or after acceptance, with the consent of the Registrar, the Board of Trade, or the Court. (17.)

Application (£1).—Any person claiming to be the proprietor of a trade mark may apply for registration. If registration is refused a written statement of grounds can be obtained and an appeal lies against the decision to the Board of Trade or the Court. (17.)

Assignment of Trade Mark.—A registered trade mark is, and is deemed always to have been, assignable and transmissible either in connection with the goodwill of a business or not. There are, however, certain conditions which are fully set out in the Act. (22.)

All assignments must be recorded in the Register. (25.)

Associated Marks.—Marks closely resembling other marks of the same proprietor already on the register may be registered subject to association with the prior mark or marks. (23.)

Portions of a trade mark may be registered as associated marks. (21.)

Several marks for the same description of goods, and similar as regards essential parts, but differing in respect of (*a*) statement of goods, (*b*) statements of number, price, quality or names of places, (*c*) other matter of a non-distinctive character not substantially affecting the identity of trade marks, or (*d*) colour, may be registered as a series of associated marks under one registration. (21.)

Associated trade marks can only be assigned or transferred together. Otherwise they are treated as independent marks. (23.)

Certificate of Registration.—Certificates of Registration are issued under the seal of the Patent Office. (19.)

Certificate of Validity.—A certificate of validity of a registered trade mark may be given by the Court and if successful in subsequent action, the proprietor may obtain full solicitor and client costs. (47.)

Certification Trade Marks.—The Board of Trade may permit the registration of a mark adapted to distinguish goods certified by any person in respect of origin, material, mode of manufacture, quality, accuracy, or other characteristic, from goods not so certified. Such a mark may not be registered in the name of a person who carries on a trade in goods of the kind certified. (37.)

Chemical Names.—No word which is the commonly used and accepted name of any single chemical element or single chemical compound, as distinguished from a mixture, may be registered. (15 (3).)

Coloured Marks.—A trade mark may be wholly or partly limited to specified colours; otherwise it is deemed to be registered for all colours. (16.)

Convention Applications.—Priority under the International Convention may be claimed provided application is made within six months of the foreign application.

Correction of Register.—The Registrar, on the request of the registered proprietor, may at any time correct errors in the name, address or description of the registered proprietor or a registered user, enter any change of name, address or description of the registered proprietor or a registered user, cancel the entry of a trade mark on the register, exclude any desired goods from the registration or enter any disclaimer or memorandum which does not extend the rights under the registration. An appeal lies to the Board of Trade or to the Court. (34.)

Costs and Security for Costs.—Registrar may award costs at his discretion and the award may be enforced by leave of the Court in the same manner as an Order of the Court. (44.)

Any party giving or contesting notice of opposition or appeal who does not reside or carry on business in the United Kingdom may be required to give security for costs. (18.)

Date of Registration.—Trade marks are registered as of the date on which the application for their registration was filed. See also 'Convention Applications.' (19.)

Defensive Trade Marks.—Proprietors of very well known invented word trade marks may obtain registration of those marks in respect of goods for which they do not use or propose to use them, provided they can show that the public would expect the mark, if used upon the additional goods, to indicate the registered proprietor. (27.)

Descriptive Marks.—Purely descriptive marks are not registrable but marks *prima facie* descriptive may become distinctive of a particular trader by long use (see under 'Registrable Marks'). Trade marks, originally distinctive, which in the course of time have come to be used in the trade in a purely descriptive way or which comprise the only practical name or description of the subject matter of an expired patent may not remain on the Register. (15.)

Disclaimers.—Registration of marks containing additional matter common to the trade, or of a non-distinctive character, may be permitted subject to disclaimer of any right to the exclusive use of such additional matter. (14.)

Discretionary Powers.—Where the Registrar is allowed any discretionary power it must not be used adversely to the applicant or registered proprietor without giving the applicant or registered proprietor an opportunity to be heard. (43.)

In appeals the Court has the same discretionary powers as the Registrar. (52.)

Duration.—Registration lasts for seven years, and is subject to renewal thereafter for periods of fourteen years without limit. (20.)

False Claim of Registration.—Any person representing an unregistered trade mark as registered is liable to a fine not exceeding £5 for each offence. The use of the word 'registered' or any other word falsely implying that registration has been obtained is not allowed. (60.)

Identical Marks.—Except as stated below, no trade mark shall be registered in respect of any goods if it is identical with or closely similar to a trade mark belonging to a different proprietor already on the Register in respect of the same goods or goods of the same description. (12 (1).)

In the case of honest concurrent user of identical or nearly identical marks or other special circumstances, the Court or Registrar may allow the registration of more than one proprietor for the same goods or description of goods with or without suitable conditions or limitations as regards mode or place of user. (12 (2).)

Where there are rival claimants to identical or nearly identical marks, Registrar may refuse to register any of them until their respective rights have been determined by the Court or settled by agreement approved by him. (12 (3).)

Infringement.—A registered proprietor may claim an injunction, damages, delivery up of infringing labels, etc., and costs in an infringement action. The validity of the registration may be attacked by the defendant by way of counterclaim. Infringement may take place either by marking goods with the offending mark, or by using such mark in advertisements or circulars issued to the public. It is not an infringement to use a registered mark on the genuine goods or so far as is reasonably necessary to indicate that spare parts or accessories are adapted to be used with the genuine goods.

Infringement by Breach of Certain Conditions.—The proprietor of a registered trade mark may by contract impose certain conditions in relation to his goods and any person having notice of such conditions and not observing them is liable to be sued for infringement. The conditions must relate to such matters as prohibition of use of the mark upon the goods after they have been altered, removal or obliteration of the mark, application of other marks or injurious matter, etc. (6.)

Inspection of Register.—The Trade Marks Register kept at the Patent Office is open to inspection by the public on payment of a fee. (1.)

International and Colonial Arrangements.—Priority based on foreign or colonial registrations can be obtained under the International Convention and International Arrangements, subject to application in the United Kingdom within six months of the basic application abroad. Patents and Designs Act, s. 91.

Lapsed Marks.—Trade Marks which have lapsed may be cited against new applications for one year after they have lapsed, unless it is proved that the mark was not in fact used for two years prior to its removal from the Register, or that no deception or confusion would be likely to arise from the use of the mark applied for. (20.)

Licences.—Licences under trade marks vitiate the validity of the mark except in the case of permitted use by registered users.

Mark.—A 'mark' includes a device, brand, heading, label, ticket, name, signature, word, letter, numeral or any combination thereof. (68.)

Merchandise Marks.—Merchandise marks include trade marks and trade descriptions and are protected in the public interest under the Merchandise Marks Acts.

Name and Address, etc., Use of.—No trade mark registration shall interfere with the *bona fide* use by any person of his own name or place of business or that of his predecessor in business, or the use of any *bona fide* description of the character or quality of the goods, provided that the description is not likely to be taken as importing a reference to the owner (or registered user) of the mark. (8.)

Non-completion.—Twelve months is allowed for the completion of registration, and after issue of a non-completion notice applications may be treated as abandoned if not completed within the time allowed in the notice. (19.)

Non-user of Trade Mark.—Any person aggrieved may apply to the Court or the Registrar for the removal from the Register, in respect of any goods for which it is registered, of any trade mark on the ground that it was registered without any *bona fide* intention to use it in connection with the goods in question and there has in fact been no user, or that there has been no *bona fide* user during the previous five years up to one month before the date of application. Non-user is not a ground for removal if it is due to special circumstances in the trade, and if there was no real

intention to abandon the trade mark in respect of the goods in question. (26). Special provision was made under Emergency legislation for protection of marks which could not be used on account of reduction of trading activities under Government orders during the war.

Opposition to Registration.—At any time within one month of the advertisement of an application in the *Trade Marks Journal*, any person may lodge opposition. The notice must state the grounds of opposition, and the applicant must file a counter-statement if the application is not to be treated as abandoned. Evidence may be filed in support of the opposition and application and after a hearing the Registrar determines whether the registration shall be allowed, and subject to what conditions, if any.

Appeal lies to the Court. No further material and no further grounds of objection may be brought forward on appeal, except by special leave of the Court. (18.)

Parts A and B of the Register.—The Register of Trade Marks is divided into two parts known as Part A and Part B. See 'Registrable Marks.'

Passing-off.—A trader has the right at common law, and apart from registration, to prevent the goods of another being passed off as his goods by reason of similarity in marking or get-up.

Prior User, Rights of.—No registered proprietor can prevent anyone else from continuing to use a trade mark which has been in use since before the date of first user of the registered mark, or the date of its registration, whichever is the earlier, nor can he object to such other person obtaining registration under Section 12 (2). (7.) See 'Identical Marks.'

Royal Arms.—The use of the Royal Arms or devices closely similar thereto in connection with any trade, business, calling or profession, so as to suggest Royal Patronage by any person not authorised may be prevented by injunction, but without prejudice to the right, if any, of the proprietor of a trade mark containing such arms to continue using it. (61.)

Rectification of Register.—Any person having good cause may apply to the Registrar or the Court to have the register corrected or rectified.

Marks may be transferred from Part A to Part B of the Register. (32.)

Registered Users.—Provision is made for the entry on the Register of the names of persons to whom the proprietor of a registered trade mark desires to allow a 'permitted use' of his mark on specified goods, provided the Registrar approves the arrangement as not being contrary to the public interest. There must be a connection in the course of trade between the registered user and the marked goods, and suitable conditions or restrictions must be laid down. (28.)

Registrable Marks.—A mark registrable in Part A must contain or consist of at least one of the following particulars :—

1. The name of a company, individual, or firm, represented in a special or particular manner.
2. Signature of the applicant or a predecessor in his business.
3. One or more invented words.
4. A word or words having no direct reference to the character or quality of the goods, and not being according to its ordinary signification a geographical name or a surname.
5. Any other distinctive mark, but names, signatures or words not complying with 1, 2, 3 or 4 shall not be registrable except upon proof of distinctiveness.

Distinctive in this section means adapted to distinguish the goods of the proprietor of the mark from those of other persons, having regard to inherent distinctiveness or actual distinctiveness acquired by use. (9.)

A mark registrable in Part B must be capable in relation to goods for which registration is sought of distinguishing goods with which the proprietor is or may be connected in the course of trade from goods in the case of which no such connection exists either generally or subject to limitations.

In the case of Part B applications importance will be attached to the extent that the mark is

(*a*) inherently capable of distinguishing.

(*b*) by reason of use or other circumstances is in fact capable of distinguishing. (10.)

All applications whether in Part A or Part B are subject to a search as to conflict with prior marks and are subject to Sections 11 and 12 of the Act, see 'Identical Marks' and 'Unlawful Marks.' The Registrar may refuse such applications or may accept them absolutely, or subject to amendments, modifications, conditions or limitations. The Registrar's decision is subject to Appeal to the Court or the Board of Trade. (17.)

Marks or any part or parts thereof may be registered in both Parts A and B by the same proprietor. (10.)

Registration for Specific Goods.—Trade Marks must be registered in respect of particular goods or classes of goods. (3.)

Registration valid after Seven Years.—After seven years the original registration of all registered marks in Part A shall be regarded as valid in all respects, unless obtained by fraud, or contrary to Section 11. See 'Unlawful Marks.' (13.)

Rights of Proprietor.—A valid trade mark registration in Part A gives to the registered proprietor the exclusive right to the use of the trade mark upon or in connection with the goods for

which it is registered, saving the rights of registered proprietors of identical or substantially identical marks. (4.)

Rights under Part B registrations are the same except that no relief can be obtained in an infringement action if the defendant establishes that the use of which the plaintiff complains is not likely to deceive or cause confusion. (5.)

Sale of Goods.—There is an implied warranty upon a sale of goods that no false trade mark has been applied (Merchandise Marks Act, 1887, s. 17). False marking may also be a breach of the conditions implied by Sections 12 and 14 of the Sale of Goods Act, 1893.

Sheffield Marks.—Subject to the approval of the Registrar, the Cutlers' Company may enter metal marks in the Sheffield Register on behalf of persons carrying on business in Hallamshire, in the County of York, or within six miles thereof, and any marks so registered shall also be entered by the Registrar in the Trade Marks Register. The Cutlers' Company is notified by the Registrar of all applications received by him in respect of metal marks. (38.)

Textile Marks.—An application for the registration of a trade mark in respect of textile goods may be made to the Registrar, either at the Patent Office or at the Manchester Branch of the Trade Marks Registry. All applications are notified to the Registrar and their allowance or refusal is determined by the Registrar subject to appeal to the Court or the Board of Trade.

In respect of textile goods being piece goods :

(*a*) No line heading alone shall be registered or deemed a ' registrable mark.'

(*b*) Registration of a trade mark shall not give any exclusive right to the use of a line heading. (39.)

Trade Mark.—A ' trade mark ' other than a ' Certification trade mark ' means a mark used or proposed to be used in relation to goods for the purpose of indicating, or so as to indicate, a connection in the course of trade between the goods and some person having the right either as proprietor or as registered user to use the mark. (68.)

Unlawful Marks.—Deceptive marks, or those contrary to law or morality, or any scandalous design, may not be registered. (11.)

SECTION XLIV

DEPRECIATION OF PLANT AND MACHINERY—INCOME-TAX ALLOWANCES

(Contributed by Alfred B. Searle, Past-Pres. Valuers' Inst., Licensed Appraiser and Valuer.)

(Pp. 1017–1021)

SECTION XLIV

DEPRECIATION OF PLANT AND MACHINERY—INCOME-TAX ALLOWANCES.

(Contributed by Alfred B. Searle, Past-Pres. Valuers' Inst., Licensed Appraiser and Valuer.)

Depreciation is a term applied to the reduction in value which occurs in plant or machinery, no matter whether they are in use or stored. The amount of depreciation is affected by the condition in which they are kept and by the availability or otherwise of more suitable appliances.

The loss in value is most properly met by an annual charge (to which the term 'depreciation' is commonly applied); the total of such charges should, when the appliance is worn out, discarded, or replaced by another, be equal to the difference between the original cost and the sum obtained (if any) by the sale of the worn-out or discarded appliance. Thus if a machine costing 1,000*l.* is discarded as useless after ten years and then is sold for only 10*l.* the total depreciation is 990*l.*, the annual depreciation is 99*l.*, and the residual value is 10*l.* The depreciation may be affected by any sums spent on renewing parts of a machine or plant though these are usually charged separately in the accounts, as *renewals*.

For methods of calculating depreciation, see p. 1019.

Deterioration is the loss in value due to the lapse of time and to the use of the appliance. It occurs more rapidly when a machine is used than when it is stored under good conditions, but may be just as serious if a machine is stored under unsuitable conditions. In deterioration is also included the loss in value which occurs directly the ownership of anything has been transferred from the seller to the buyer, the 'second-hand value' being always less than the market price when new; the difference forms part of the loss by deterioration.

Obsolescence is the loss in value which occurs when a more suitable appliance can be used for the same purpose. It occurs when a machine is discarded, long before it is worn out, because another machine is more profitable to use.

Renewals are the cost of replacing worn-out or damaged portions of machinery or plant. To some extent they reduce the depreciation, but for convenience are usually treated quite separately. The Inland Revenue officials for some purposes, take renewals instead of depreciation when calculating allowances for income-tax assessments. Thus, instead of allowing 3*l.* per annum as the depreciation on a typewriter, they allow nothing until the typewriter is replaced by another one; then they allow the cost of the new machine less the sum obtained by the sale of the old one, or a sum estimated to be obtainable for it.

Repairs are essential to the maintenance of machinery and equipment in good condition but, as it is almost impossible to estimate their cost long before they are required, no allowance is made for repairs when calculating the allowance for depreciation.

Residual Value is the value of a machine or plant at the end of a given period—usually, but not necessarily, when it is worn out or discarded. In dealing with the estimated life of plant or machinery, the residual value of such plant or machinery when its period of usefulness has expired must be taken into account, and with plant of special nature it may generally be assumed that in proportion to its special character its residual value will be low Plant of general character, engines, boilers, shaftings, pulleys, etc., carries a high residual value in the event of displacement.

Diminishing Value is the reduction in the value of plant or machinery as the result of depreciation or obsolescence, or both. The term is also used to indicate the value obtained by deducting depreciation for one year at a given rate, and then applying the same rate to the reduced value so obtained. Thus, if a machine costing 1,000*l.* is depreciated at 10 per cent. per annum on the diminishing value it will be worth 900*l.* at the end of the first year, 900*l.* − 90*l.* or 810*l.* at the end of the second year, 810*l.*—81*l.* or 729*l.* at the end of the third year, and so on. This method is largely used because of its convenience, but it requires a larger rate of depreciation than when the

rate is calculated thoughout on the original value. In recent years there has been a tendency to revert to the basis of original cost. For instance, a rate of 10 per cent. on the original cost will exhaust the value in ten annual instalments; but a rate of about 16½ per cent. would be required to exhaust the value in the ten years if calculated on the diminishing value remaining after the deduction of depreciation in each year.

The argument in favour of basing the calculation on the diminishing value is that the sums written off in the earlier years were greater when the repairs were small, and this tended to equalise matters. Too often, however, the two factors of rate and basis have not been settled together, and consequently the basis of diminishing value has had the effect of leaving a considerable value in the books when the plant has disappeared. For instance, a 5 per cent. rate generally carries the impression of a twenty years' life, yet taking 100*l.* as the cost, and writing off on the diminishing value, the balance left at the end of the twentieth year is 37*l.* 14*s.* After twenty-one years' service the residual value of the plant would be, roughly, one-third of the first cost a figure far too high in most cases.

Rate of Depreciation.—There are several methods of calculating the amounts to be set aside annually for depreciation. One of the most widely used—but not necessarily the best—is to deduct a pre-arranged percentage of the original cost of the machine or equipment. This simple method has serious objections in some cases (see p. 1019). The determination of the rate of depreciation of various kinds of machines, etc., requires special skill and experience, and has given rise to specially trained appraisers or valuers, each of whom has expert knowledge of certain classes of plant or machinery; a valuer who is an expert on brewing appliances would probably know little of cotton-spinning, bricks, or presses, and *vice versa*. It is, therefore, important that valuations should be made by men of *special* knowledge and not (as is usually the case in valuations for rating assessments and some other purposes) by men with only a general knowledge.

As different parts of a plant and different machines wear out or become obsolescent at different speeds, it is desirable to decide on a rate for each separate machine or appliance, though some grouping is desirable.

There is much difference of opinion as to what are suitable rates of depreciation, especially when accurate data on which to base them are not available. For several years past the great increases in the cost of machinery and other equipment has resulted in all allowances for depreciation being much too low. A correct allowance would enable a new machine to be purchased with the total sum set aside for depreciation plus the proceeds of sale of the old machine. At present, new machines cost so much more, that the depreciation allowance may not equal more than half the cost of a new machine. This fact should be borne in mind when calculating rates of depreciation.

The following figures are only approximate, but they give a useful *general* idea, which may be greatly modified in particular cases.

Motive Power, Boilers, Engines, etc.—Some authorities place the depreciation on engines as high as 12½ per cent., and boilers at 10 to 15 per cent. Much depends on stress of working and the water. Mathieson places the life of a boiler at fifteen years, with renewal of the furnace at the end of ten years, and recommends a rate of 7½ per cent. per annum on the diminishing value on this class, no provision being made for obsolescence. This is, however, an extreme view.

Power Transmitters.—Shafting, pulleys, and plant under this head have, as a rule, a high residual value, even if displaced, and a rate of 5 per cent. will usually be found sufficient. Belting should be classified as loose tools. In this class a rate of 10 per cent. would be desirable. No provision is made for obsolescence.

Process Plant, Fixed.—Under this head would be placed all heavy process plant, the renewal portions of which are classified under their separate heading. The deterioration would then be met by a rate of 10 per cent. With a lesser rate, an obsolescence rate depending on the nature of the processes will also be needed; it may be 6 per cent.

Process Plant (Wearable).—For this it is necessary to provide a heavy renewal rate. By the dissection of this plant the separation of the different details can be secured, and it is easy to apply to each a distinctive rate for renewals applicable to its character and requirements, based on experience. It will usually be at least 10 per cent., and may be 50 per cent.

Process Plant (Loose).—In the case of loose tools, the yearly valuation gives the most reliable results. In some cases there is an annual increase in this class, but this should verify itself. It is to be remembered that a going-concern valuation can seldom work out at more than half the original cost value. Hence, the depreciation on loose tools and on some parts of process-plant should be at least one-third of the original cost.

Accessory Plant.—Usually has a high residual value due to general utility, and consequently a rate for deterioration of 5 per cent. and a renewal rate of 10 per cent. should suffice.

Horses, Carts, Harness, etc.—The risks and depreciation on this class are too great to include in any average rate. A revaluation annually gives probably the best results.

The following table gives (A) the approximate life in years of the various classes of machinery etc., in an electrical undertaking if properly maintained, and (B) the probable residual value at the end of that term in per cent. of original cost. It affords a useful means of checking any suggested rate of depreciation on the applicances, etc., mentioned, but is very incomplete and some figures in column A are too large for many conditions.

	A.	B.		A.	B.
Accumulators	15	10	**Electric motors**	15	9

QUINQUENNIAL VALUATIONS.

It is very important that an independent valuation of all land, buildings, plant, and machinery should be made by a qualified valuer at least once every five years.

Such a valuation if properly made will correct any errors due to wrong rates of depreciation and to over-valuation of assets. It will enable the accountants to prepare a more satisfactory balance sheet and will, in many cases, save much disappointment and loss.

Many large engineering firms rightly attach great importance to these five-yearly valuations and find them invaluable in many ways.

It is essential that such valuation should be made by a Valuer having special knowledge of the articles to be valued. A Valuer accustomed to doing mainly the work of an Auctioneer cannot be expected to have the necessary special knowledge.

METHODS OF ESTIMATING DEPRECIATION.

Appraisers and valuers have various methods of estimating the depreciation of plant and machinery, and two men of equal skill may not agree in their estimate because they use a different method, or because they have different ideas as to the durability of a particular appliance; the latter affects the rate of depreciation. Several methods of estimating the allowance to be made for depreciation are, therefore, in use, viz :—

(1) The *Residual Value* (p. 1017) is deducted from the original cost and the difference is divided by the number of years which the machine or equipment is expected to be in condition, suitable for its satisfactory use. By this means, the same amount is deducted each year so that at the end of the period the total of the sums so deducted plus the amount for which the machine or equipment can be sold will equal its original cost.

(2) The *Diminishing Value* (p. 1017) is calculated year by year and the resulting figure is the amount allowed for depreciation. Unless special care is taken this method tends to give too low a result (see p. 1018), and the calculation are much more tedious than those in method (1).

A Table showing Diminishing Values is shown on p. 1024.

The chief advantage of using the method of Diminishing Values is that it enables large deductions to be made when the machine or equipment is new and the cost of repairs and renewals is likely to be small, and smaller deductions are made when the cost of repairs and renewals will probably be greater. By this means the *total* annual charge will be kept more constant.

(3) *Amortization* is, theoretically the best method, either a *Vertual Rent* being charged or a *Sinking Fund* created. This method is only suitable when the amounts set aside annually are actually reinvested at the rates of (compound) interest assumed in the calculations. If no such investment is possible amortization will give far too low a figure for depreciation.

If the annual allowances calculated by methods (1) and (2) are merely placed in a box, their total, at the end of the period, will be precisely the sum accumulated. If, however, each regular payment is promptly invested at a suitable rate of interest and the interest each year is also invested at the same rate, the sum finally accumulated will be considerably larger than the total of the regular payments. For instance, the regular payment of £84 per annum and its prompt investment at 3 per cent. per annum compound interest would complete the repayment of a Loan of £1,000 at 3 per cent. per annum in 15 years. If only a lower rate of interest is allowed the time taken would be correspondingly longer.

In calculating amortization there are two distinct aims to be considered :—

(a) The accumulation of an agreed sum at the end of a specified number of years. For this purpose a *Sinking Fund* consisting of regular annual payments, suitably invested will suffice. Each payment must then be the sum which, under the prescribed conditions, will, with interest, provide the desired amount. The annual payment required can be calculated mathematically or ascertained from Sinking Fund Tables.

(b) The accumulation of an amount which will extinguish a loan and also repay the annual interest on the loan is best effected by the payment of a *Virtual Rent*, which can also be calculated mathematically or ascertained from Virtual or Sitting Rent Tables.

The great difficulties, at the present time, in investing regular amounts at compound interest have made amortization a matter of great uncertainty and many engineers and others tend to ignore its possibilities and so suffer a corresponding loss.

One very convenient method of amortization is to arrange an *Endowment Insurance Policy* with a reliable Company, so as to provide the sum required at the date arranged. The premiums paid for such a policy will be the amounts set aside for depreciation or obsolescence or for the repayment of a loan and will be entered as such in the accounts. Such a policy can be based on the amount which will be required to purchase a new machine or equipment at the end of the period and can therefore provide for increases in the cost in a manner not allowed for by other methods.

(4) *Valuation.*—The machine or equipment is valued each year by a skilled valuer and the difference between this figure and that in the Accounts is allowed for depreciation. This method is not used each year but at intervals of five or more years. In the intervening periods one of the other methods is used.

(5) *The Inland Revenue* in some cases, makes allowances on renewals instead of a depreciation allowance (see *Renewals*, p. 1017 and *Income Tax*, below).

None of these methods are wholly satisfactory because of the complex nature of the problems involved. Thus, if a machine or equipment is valued as a whole the allowance may be too low, because different parts depreciate at different rates, and no single figure or ' average ' can be accurate. Even if the plant and machinery are divided into groups or each individual item is taken separately errors may still occur, as it is by no means easy to find an accurate rate of depreciation for some appliances. A common device is to divide the plant and machinery into five or more groups, make a separate valuation of each group, and to adjust this by a revaluation by an expert every five years. This is probably the best compromise between accuracy and cheapness.

A distinction must be made between the first and second method for they do not necessarily yield the same results.

Revaluation by a professional valuer is so expensive that it can seldom be done annually, though a yearly valuation of some of the machinery and tools may best be made by this means.

The last method (renewals) is only satisfactory for relatively small appliances costing not more than £50 and requiring to be replaced every few years (see p. 1021).

***Fire Insurance and Depreciation.*—Whilst it is a sound, general policy to write as much off for depreciation as possible, such a course has an adverse effect on insurance against fire, as the value in the case of a fire would be affected in the claim for replacement. It is usual in some offices to append a declaration on the face of the policy that the depreciation written off in the books shall not be taken for the purpose of assessing a fire loss. Usually the assured is covered for the value of the plant at the time of the fire, and that the original cost of the plant, less depreciation, is not necessarily the basis of the claim. There appears to be no scale of depreciation in force for different kinds of plant recognised by the insurance companies, but these losses are generally settled as between the assessors and surveyors acting for both parties, or, failing their agreement, by arbitration : no special rates are applicable, but each case is settled on its merits. The principal factor appears to be the possession of definite and specific information on the value and cost of the plant, and the rate of depreciation should not in any way govern the claim in case of fire.**

It is a general provision in fire insurances and policies that the company may elect to replace the plant ; instances of this have rarely occurred, if ever, and probably the replacement clause was never intended as other than a protection to the insurance company.

***Depreciation and Income-Tax.*—The rate of depreciation allowed by the inspectors appointed under the Income-tax Acts differs considerably in different localities. For instance, the rate of depreciation allowed to engineers in Leicester is 7½ per cent. on the full value, while in Cardiff the rate is only 5 per cent. on the diminished value. Hosiery machinery in Leicester obtains 7½ per cent. as against 5 per cent. on lace machinery in Nottingham. Dyers' machinery in Leicester can get 10½ per cent., if justified on inquiry. Generally speaking, a distinction is made between motive power and process plant, and the general practice assumes 5 per cent. on motive power and 7½ per cent. to 10 per cent. on process plant ; these allowances are in respect of both deterioration and renewals.**

The Association of British Chambers of Commerce in 1933 reached a series of Agreed Normal Rates of Depreciation Allowances with the Inland Revenue. Those relating to Engineering are shown below; all are on the *written down value*.

	Per cent.
Brass foundries general plant and machinery	7
Colliery surface plant (not electrical)	6¼
Colliery underground plant	10
Drop forgers and stampers general plant and machinery (excluding furnaces)	7½
Electric furnaces and plant and machinery used in connection, but excluding foundations, buildings, cranes, buckets, shop tools or equipment	12½
Electric light undertakings:	
Cables	3
Plant and machinery	5
Electric motors, dynamos, and other electric plant	7½
Engineers precision tools, manufacture of such as twist drills, milling cutters, reamers, tap dies and screwing tackle, but excluding engines, boilers, shafting, pulleys, and electrical plant	9
Engines, boilers, shafting	5
Lorries driven by internal combustion engines	20
Lorries (steam)	15
Pig iron and steel manufactures, on general plant and machinery, but excluding furnace structures	7½
Railway wagons owned by traders	6¼
Refrigerating machinery, compressors, condensers, ice tanks, coolers, conduits, moulds, coils, travellers, etc.	10
Saw mills (sawing plant only)	7½
Wrought iron industry general plant and machinery	7½

Where plant and machinery is used by night as well as by day no extra allowance for steam raising plant, but an additional 25 per cent. of the normal rates on all other plant run both day and night. No allowance for less than 24 hours per day.

Furnaces and kilns: no depreciation allowance, but the cost of repairs, renewals, and rebuilding are allowed against revenue. Extensions and enlargements to be charged against capital.

Lagging, belting, loose plant, and utensils to be dealt with by way of renewals.

The Inland Revenue authorities have now reverted, in a number of cases, to the basis of original cost, and where, say, 5 per cent. is allowed on original cost, there is an alternative rate of 7½ per cent. allowed on diminishing value.

On *Fixtures* no allowance for depreciation is made, unless they are rightly included under the head of plant. Any replacements are allowed in full against the year's working.

Renewals.—The practice adopted by the income-tax authorities provides for the charging up of renewals to capital account where depreciation is allowed, and they usually decline to allow both renewals and depreciation out of the year's profits. They will, however, permit, as an alternative to the allowance for wear and tear and obsolescence of plant and machinery, the cost of renewing plant and machinery, under Schedule D. When this course is adopted, the amount to be allowed is the actual cost of the new plant and machinery (excluding any part of such cost which is attributable to additions or improvements, *i.e.* to an increase in capital) after deducting the scrap value or realised price of the plant and machinery replaced.

Example (a).—A machine which originally cost 1,000*l.* is worn out and replaced by a machine of similar power or size or capacity which now costs 1,500*l.* The whole of this expense of 1,500*l.* less, say, 100*l.*, the scrap value of the old machine (making a net amount of 1,400*l.*), is allowable from the profits of the year in which it is incurred.

Example (b).—A machine which originally cost 1,000*l.* is worn out and replaced by one of greater power or size or capacity costing 2,500*l.* The amount to be allowed as an expense is in this case not the full 2,500*l.*, but only the cost of replacing the old machine by one of similar power of capacity, say, 1,500*l.*, less the scrap value of the old machine.

Although this method of allowance is alternative to the wear and tear allowance for the same class of plant, the two principles may run concurrently for different classes of assets in the same business. For example, the wear and tear allowance may be applied to fixed machinery, and the renewal method used for loose plant.

Example (c).—Assuming the total written down value of the trader's plant and machinery before the sale of the obsolete machine to be 10,000*l.*, the new machine to cost 1,400*l.* and the old one to be sold for 400*l.*, future wear and tear allowances will be made upon a value of 11,000*l.*, thus:—

	£
Written down value of total plant, etc.	10,000
Deduct written down value of the obsolete machine	400
	£9,600
Add cost of new machine	1,400
	£11,000

The *Wear and Tear Allowance* was formerly based on the average of the preceding three years' trading, but in 1927 this was stopped and since then only the preceding year is taken into account.

If the allowance for wear and tear exceeds the assessable profits, the excess may be carried to the following year's assessment. Thus:—

	£
Gross assessment, 1927–8	6,000
Wear and tear allowance, 6,500*l*., of which 6,000*l*. is allowed for 1927–8 and 500*l*. is carried forward	6,000
Net amount on which tax is payable for 1927–8	nil
Gross assessment, 1928–9	7,600
Wear and tear allowance, 6,800*l*. for 1928–9 plus the unexhausted balance carried forward for 1927–8, 500*l*.	7,300
Net amount on which tax is payable for 1928–9	£300

Another example of wear and tear allowance is as follows:—

Example.—A machine is purchased on May 10, 1949, for £200, sold on November 18, 1951, for £110 and replaced by another costing £224. The rate of depreciation allowable is 7½ per cent. per annum.

		£	£
1949–50.	Cost Price	200	
	Wear and Tear 7½%		15
	+ one fifth allowance		3
	Total allowance for year		18
1950–51.	Written-down Value	185	
	Wear and Tear 7½%		14
	+ one fifth allowance		3
	Total allowance for year		17
1951–52.	Written-down Value	171	
	Wear and Tear 7½% for 6 months		6
	+ one fifth allowance		1
	Total allowance for year £7		7
Claim.	Written-down Value	165	
	Less three one fifth allowances		7
	Less Sale Price		110
		117	£117
	Obsolescence Claim 1951–52	£48	

No allowance is made on the increased cost of the new machine.

A special loose-leaf book, showing all details of cost, written-down values, allowances and price obtained on sale should be kept up-to-date. It is best to have the particulars of each separate machine entered on a separate page. Such a book can be shown to H.M. Inspector of Taxes, if equired, and often facilitates the granting of the allowances claimed.

IMPORTANT.—It frequently occurs that machines wear out more rapidly or have, for other reasons, to be replaced sooner than the allowable rate of depreciation provides. For this reason, the rate of depreciation and obsolescence in the firm's accounts may, rightly, be much larger than those allowed by H.M. Inspector of Taxes. This is particularly the case when machines are worked continuously on two shifts or are subjected to any other cause of additional wear and tear.

AGREED RATES OF NORMAL DEPRECIATION ALLOWANCES.

The National Federation of Clay Industries in 1938 agreed to the following with the Income Tax Commissioners:—

	Per cent.
Kilns for bricks tiles, etc.*	8
(Cost of repairs and renewals of parts is allowed as an ' expense ')	
Chimneys (if an integral part of a kiln) *	10
If the kiln could be replaced without affecting the chimney, it is to be treated as a separate structure, it is to be excluded from the wear and tear or renewals computation	—
Dryers (either Tunnel Dryers or Sheds) are eligible for renewals allowances	—
Brickmaking machinery	5
Boilers	5
Mixing Machines	5
Steam Engines	5
Shafting	5
Electrical plant	7½
Crushing and grinding plant	7½

* Alternatively, an arrangement for renewals may be made.

All additions to and replacements of plant and machinery to be charged to capital *except* those renewals and replacements which do not destroy the identity of the machine (these being allowed as an expense).

An additional allowance of one-fifth under S. 18 of the Finance Act (or subsequent Acts) is applicable to all allowances for wear and tear.

Commercial Rates of Depreciation.

The rates of depreciation allowed by the Inland Revenue Department are much lower than those considered to be prudent by many valuers and other authorities. It is therefore wise to include in a firm's accounts allowances for depreciation, etc., which are suitable for that particular business and not to suppose that the allowances permitted by the Inland Revenue Department are sufficient for the best interests of the firm.

No single set of figures can apply to all cases, but the following will be found to be as safe as any such general figures can be. In each case other factors, such as the probable duration of the business, must be taken into account.

	Per cent.
Air compressing plant (whole)	10
Air compressors	5·5
Autoclave	8·5
Belting (driving), leather	20
" " rubber	25
Belting (conveyor), canvas	40
" " rubber	30

Special Allowances.

Special concessions are being arranged by the Inland Revenue Authorities, so as to enable **the burden of the increased income tax to be removed from industry. These take the** form **of increased allowances for depreciation. Particulars can be obtained from local** Inspector **of Taxes.**

Rating Allowances.

The changes effected by the recent Rating Acts are so numerous and so serious that very little guidance can be given in these pages. The soundest procedure is to employ a skilled valuer and an equally skilled accountant and, where practicable, to obtain a 'settlement by consent.'

To avoid unnecessary litigation in the form of appeals it is customary for such valuers to place a lower value on the assessed property than it would realise if sold to a willing buyer as part of a (successful) going concern.

It is increasingly becoming the custom to base rating assessments on the output or sales, and although this is not strictly legal it is often accepted as convenient to all concerned. Thus, a stone-quarry may be assessed : (*a*) on the unworked land in reserve, and (*b*) on the output or sales, the latter being assessed at 9*d*. per ton or some other figure. Similarly, a brickworks may be assessed in three parts : (*a*) the unworked land (held in reserve) on an agricultural or surface-rent ; (*b*) the buildings and plant at (say) £100 per annum as a nominal figure, and (*c*) the clay at (say) 9*d*. per thousand bricks produced. A further simplification is sometimes effected by combining (*b*) and (*c*) into a single figure, such as 1*s*. 0*d*. per thousand bricks produced.

Many industrial properties are now de-rated, but the calculations necessary in this connection cannot be explained briefly. The officials of the local Rating Authority will usually afford ample information, but they do not always interpret the law correctly as to whether a particular property or what parts of it should be de-rated.

Important Note.

The 1939–1945 war in Europe has caused so much abnormal wear and tear on buildings, plant and machinery used by many firms that it is necessary in many cases to take this specially into consideration. The calculation of *obsolescence* is similarly affected.

Patents.

The Income Tax Act, 1945, makes special provisions for writing off the value of Patents.

SECTION XLV

LEGAL NOTES FOR ENGINEERS.

(Contributed by Sir W. Valentine Ball, O.B E., M.A., Barrister-at-Law.)

(1) LEGAL STATUS OF AN ENGINEER. (2) FEES. (3) EMPLOYMENT OF AN ENGINEER. (i.) *Generally;* (ii.) *Employment Abroad:* (iii.) *Wrongful Dismissal;* (iv.) *The Restrictive Covenant;* (4) SECRET COMMISSIONS. (5) DISCLOSURE OF SECRETS. (6) RIGHTS OF AN ENGINEER TO THE INVENTIONS OF A SERVANT. (7) THE ENGINEER AS WITNESS. (i). *Generally;* (ii.) *Arrangements as to Fees;* (iii.) *Evidence before Parliamentary Committees.* (8) THE COURT EXPERT. (9) LIABILITY FOR NEGLIGENCE. (10) RIGHTS, POWERS, AND DUTIES OF AN ENGINEER UNDER A CONTRACT FOR WORKS. (i.) *Generally;* (ii.) *Specifications;* (iii.) *Plans and Drawings:* (iv.) *Extras;* (v.) *Certificates;* (vi.) *Penalties and Bonuses;* (vii.) *Defects, Repairs, and Maintenance;* (viii.) *Sub-contractors and Specialists,* (ix.) *Whether the Employer's Engineer can act as Arbitrator in Relation to Disputes Arising under a Contract.* (11) THE ENGINEER AS ARBITRATOR. (i.) *Generally;* (ii.) *Who may be Arbitrator:* (iii.) *Proceedings before the Arbitrator;* (iv.) *The Award;* (v.) *Time for Making the Award;* (vi.) *The Fees of an Arbitrator;* (vii.) *Stating a Case for the Opinion of the Court;* (viii.) *Costs of a Reference.* (12) NOTES ON SALE AND PURCHASE OF MACHINERY.

(1) LEGAL STATUS OF AN ENGINEER.

Any person may describe himself or practise as an engineer, as the word engineer is not a term of art in the legal sense. Although the Institution of Civil Engineers may make rules of professional etiquette to be observed by its members, compliance with such rules will not be enforced in a court of law, save in so far as they involve a restatement of the ordinary law. For instance a rule which states that no consulting engineer shall advertise could not be enforced, whereas infringement of a rule that 'he shall not pay by commission or otherwise anyone who introduces clients' might offend against the common law (*Panama Telegraph Co.* v. *India Rubber Co.* (1875) L. R. 10 Ch. 515) or against the Secret Commissions Act.

(2) FEES.

If an engineer is consulted, there is an implied contract to pay him reasonable remuneration (*Munson* v. *Baillie* (1855) 2 Mac. H. L. Cas. 80). It is more satisfactory, however, to provide for payment of fees beforehand. In the case of a contract to design and supervise erection of works it is well to provide for payment of ⅓ on signing the contract, ⅓ when half the contract price has been paid to the contractor, and ⅓ when the contractor has been fully paid. Provision should also be made for (1) payment for plans and drawings in case the works are abandoned; (2) travelling and hotel expenses. There is, of course, no fixed scale of remuneration for the engineer, but in deciding what is a reasonable charge, the Court would have regard to (i.) the standing of the engineer; (ii.) the nature and extent of the work undertaken and carried out. It is no answer to a claim for fees (*a*) that a particular undertaking has proved to be a failure if the failure was not due to any fault of the engineer—as where, for instance, an engineer is employed merely to *supervise* the erection of a dam which bursts on completion; or where an engineer is employed to draw plans for a newly invented machine which fails to work (*aliter* if the employer was relying on the engineer's skill and judgment: *Duncan* v. *Blundell* (1820) 3 Stark. N.P. 6); (*b*) that the work in question is not completed, if the failure to complete is not due to the engineer. Where an engineer is to be paid on completion and the work is abandoned before the time, the engineer is entitled to what is due for services rendered, and to what he has lost by not being allowed to complete the contract (*Horton* v. *Hemsley* (1908) *Times*, February 19).

(3) EMPLOYMENT OF AN ENGINEER.

(i) Generally.—Where an engineer is to be employed for more than a year certain, the agreement must be in writing; and this is so, even if the employment is terminable at any time by six months' notice on either side (*Hanau* v. *Ehrlich* (1912), A.C. 39). The document must set forth all the terms. It is safer, however, to have the terms of an agreement always put into writing. Special care should be taken to (*a*) specify the times when the salary is to be paid; (*b*) provide for the contingency of illness, as illness does not necessarily determine the contract, nor will it justify dismissal without regular notice, unless the employee is so smitten with disease that he can never be expected to work again (*Cuckson* v. *Stones* (1858) 1 E. & E. 248); (*c*) provide for the notice which may be given on either side to determine the contract. If nothing is specified in the agreement, an engineer employed at a yearly salary is entitled to a year's notice (*Buckingham* v. *Surrey and Hants Canal Co.* (1882) 46 L. T. 885). An engineer wrongfully quitting his employment without notice forfeits the salary due for the part of the current year which he has served. The fact that a contract of employment for an indefinite period contains no express term as to notice to be given for its determination does not exclude the implication that such a notice is required (*Payzu* v. *Hannaford*, 34 T. L. R. 442). The suspension of servant from his duties which prevents his earning his commission may amount to a wrongful dismissal (*Rubel* v. *Vos*, 34 T. L. R. 171). Dismissal without notice is only justifiable in a case of gross misconduct. If the 'employer' is a company or a municipal corporation or other local authority it is safer to insist that the contract be under seal. The Public Health Act, 1875, s. 174 (1) provides that every contract made by an urban authority whereof the value or amount exceeds 50*l*, shall be in writing and sealed with the common seal of such authority. A surveyor who prepared plans for a local board under a verbal contract was held entitled to recover nothing (*Hunt* v. *Wimbledon Local Board* (1878) L. R. 4 C. D. D. 48). Close examination of a contract between an engineer and a local authority may, however, show that it is not within this section (see *Douglass* v. *Rhyl U.D.C.* (1913) 2 Ch. 407). Where the engineer is in the employment of a local authority he must have no interest in any contract into which that body enters (see *Mellis* v. *Shirley Local Board* (1885) L. R. 14 Q.B.D. 911). An attempt was recently made to raise the question whether a consulting engineer is liable to pay excess profits duty under s. 39 of the Finance Act, 1915, but the Court of Chancery refused to decide the point, leaving it to the King's Bench Division (*Smeeton* v. *Attorney General* 35 T. L. R. 706).

(ii.) Employment Abroad.—Where an engineer is about to accept employment abroad, he should be careful to see that provision is made for the payment of travelling and other expenses. No agreement to pay travelling expenses would be implied from an undertaking, say, to employ an engineer at a salary of 1,000*l*. a year at Malacca as from January 1, 1933. It is also well to provide in the agreement that any disputes which may arise shall be determined either by arbitration or according to English law.

(iii.) Wrongful Dismissal.—If an engineer is wrongfully dismissed, it is his duty to reduce the damages as far as possible by taking other employment if he can procure it (see *Storey* v. *Fulham Steel Works* (1908) 23 T. L. R. 306). The damages are then ascertained by subtracting what he has earned from what he would have earned.

(iv.) The Restrictive Covenant.—When employing an assistant, an engineer may find it necessary to bind him not to set up close by in competition. A restrictive covenant is legal, if it is not too wide; it must be only what is reasonably necessary for the protection of the parties. A covenant to prevent a dentist practising within 200 miles of York was held to be too wide (*Horner* v. *Graves*, 7 Bing. 735). On the other hand, a covenant which bound a canvasser not to enter an employment 'within twenty-five miles of London where the plaintiffs carry on business' was held by the House of Lords to be unreasonable (*Provident Clothing and Supply Co.* v. *Mason* (1913) 29 T. L. R. 727). Care should be taken not to make the restriction perpetual unless that is absolutely necessary, for the Court criticises a perpetual covenant more closely (*Eastes* v. *Russ* (1915) 30 T. L. R. 237). In a recent case the validity of a covenant affecting a man who was employed as works engineer at a bottleworks was considered (*Forsters* v. *Suggett*, 35 T. L. R. 87).

(4) SECRET COMMISSIONS.

The receipt of a secret commission or a bribe by an engineer would clearly justify his dismissal (*Boston Deep Sea Fishing Co.* v. *Ansell* (1883) 39 Ch. D. 339). In such a case there is a presumption that he was influenced, against his employers' interest, by the bribe (see *Hovenden* v. *Millhoff* (1900) 83 L. T. 11).

(5) DISCLOSURE OF SECRETS.

An engineer may be employed to do work of a confidential nature for others; or he may have to employ workmen to do confidential work for him (*e.g.* by employing a workman to make a model of a new and patentable machine). The law implies an agreement by the servant to keep his master's secrets, and he may be restrained by injunction from disclosing them (*Alperton Rubber Co.* v. *Manning and Others* (1917) 116 L. T. 499; 33 T. L. R. 205).

(6) RIGHTS OF AN ENGINEER TO THE INVENTIONS OF A SERVANT.

If a servant invents a machine in his employer's time and even when using his employer's materials, the invention does not become the property of the employer so as to prevent the servant taking out a patent for it (*Heald's Case*, 8 R. P. C. 430). But if the servant were to steal an idea and endeavour to patent it either before or after the termination of the service, the employer could oppose the grant of a patent in respect of it (*Thwaites' Application*, 9 R. P. C. 515). And if the servant obtains a grant of a patent in respect of the invention, he can only hold it as trustee for his employers (*British Reinforced Concrete Engineering Co.* v. *Lind* (1917) 33 T. L. R. 170). The engineer when employing a servant should take care to provide, by the agreement, that the inventions of the servant shall belong to him; but when himself entering into a contract of service he should be careful to sign nothing which will abrogate his rights.

(7) THE ENGINEER AS WITNESS.

(I.) Generally.—As the engineer frequently comes into contact with the law and the lawyers in the capacity of a *witness*, a few notes of a practical character on the duties of a witness may be found useful.

When invited to give evidence as an expert the engineer should: (*a*) arrange for a qualifying fee to be paid in any event; (*b*) examine the plans and documents, and, if necessary, obtain a view of the *locus in quo* before consenting to give evidence; (*c*) warn the parties consulting him of all the difficulties which are manifest to him; (*d*) ascertain, if possible, the contentions which are going to be put forward by the other side, and make himself familiar with any views which they may have published upon the matters in dispute. Having consented to give evidence, the engineer should (*a*) be ready to satisfy the lawyers with regard to any technical point which may be raised in consultation; (*b*) listen to the arguments and evidence in Court, and be prepared to deal with any points made by witnesses on the other side; (*c*) bring with him any entries in his diary or any notes which he may have made *at the time* with reference to the matters in dispute, for he may use such notes to refresh his memory. Thus, if an engineer has to report as to the condition of a structure, he may use in the witness box the notes which he made on the spot. But he could not use a copy of such notes unless he was prepared to produce the original; (*d*) make and bring to court a plan or model of the structure or machine under discussion, as this will save much wordy explanation; (*e*) search in libraries and in the published proceedings of the various institutions for any books and papers dealing with the matters in hand—especially any papers written by himself, in order that he may not be confronted with an adverse opinion given on a former occasion. A witness should bear in mind that it is his duty to state facts and express opinions, not to advocate the cause. As soon as he appears to be taking a biased view or attempting to fight the case it is more than likely that the tribunal will pay little heed to his evidence. A candid answer to an awkward question is often less dangerous than a long and evasive statement. In *Crosfield and Sons, Ltd.* v. *Techno-Chemical Laboratories Ltd.* (1913, 29 T. L. R. 378) Neville, J., expressed some views as to the function of an expert witness which may be thus summarised:—

(*a*) It is not competent in any action for witnesses to express their opinion upon any of the issues, whether of law or fact, which the Court or a jury has to determine.

(*b*) In patent cases, expert evidence is often necessary (i) to explain words or terms of science or art, or to inform the Court in case the import of a word in a document to be construed differs from its popular meaning; (ii) to instruct the Court in the laws of science; (iii) to describe the state of public knowledge at the date of the patent. 'It is rare,' added his lordship, 'to find any substantial difference of opinion between eminent experts upon matters of science whenever it is possible to dissociate the question from immediate connection with the issues in the action.'

(II.) Arrangements as to Fees.—On being *subpœnaed* one is bound to attend as a witness provided sufficient conduct money is paid with the subpœna. Failure to attend might lead to an action for damages, while in the County Court the judge has power to fine a witness for non-attendance. A witness may refuse to give evidence until his expenses have been paid (*Newton* v. *Harland* (1840) 1 M. & G. 956). It should be noticed that the person liable to pay the fees is the party to the litigation, not the solicitor, unless he has expressly made himself liable (*Lee* v. *Everest* (1857) 26 L. J. Ex. 334). In order to save trouble it is best to arrange for and if possible secure payment of fees in advance. The fees 'allowed on taxation,' that is to say, the fees which an unsuccessful litigant will be ordered to pay in respect of witnesses called by the other side, are very small, but the party calling the witness will have to pay his agreed fee whatever it is. Where a case is tried at assizes in the town where the engineer lives or in London (when the engineer lives in London), the fee allowed is 1*l*. 1*s*. *per diem*, or where the engineer lives away from the town 1*l*. 1*s*. to 3*l*. 3*s*. But the taxing masters may also allow a qualifying fee of so much a day varying with the magnitude of the case. In 1875 a fee of 7*l*. 7*s*. was not considered excessive payment to a scientific witness. It is probable that a larger sum would be allowed at the present day. In addition he is allowed the travelling expenses reasonably and actually paid. In County Courts the fee allowed for qualifying to give evidence on Scale B is 1*l*. 1*s*. to 3*l*. 3*s*.; on Scale C, 1*l*. 1*s*. to 5*l*. 5*s*.; for attending Court on trial (*per diem*), Scale B, 1*l*. 1*s*. to 2*l*. 2*s*.; Scale C, 1*l*. 1*s*. to 3*l*. 3*s*.

The above scales were fixed before the war, and have not been altered. So far as they can the taxing masters will probably grant the maximum owing to high prices.

(iii) Evidence before Parliamentary Committees.—When an engineer is summoned to appear as a witness before a committee of either House of Parliament he looks for his fees to the party who summons him—whether he is the promoter or an opponent. According to May's 'Parliamentary Practice' (1906), p. 434, an engineer summoned as a witness before a committee should report himself to the committee clerk on his arrival in London, or he will not be allowed his expenses for residence prior to the day of making his report; *3l. 3s.* a day is the parliamentary allowance, but of course as between the engineer and the party summoning him the *quantum* of the fee is a matter of agreement.

(8) COURT EXPERT.

The Rules of the Supreme Court enable the Court to appoint what is called a 'Court Expert,' being a person whose status is intermediate between that of a 'witness' and an 'assessor.' He is appointed at the instance of any party to a suit, to report on any question of *fact*. His report is treated as information supplied to the Court, and the writer of it may be cross examined upon it. (For further information as to the Court Expert, see Order 37A of the Rules of the Supreme Court.) An engineer should consult his solicitor before accepting this *rôle*, because the position with regard to his claim for fees is not very satisfactory.

(9) LIABILITY FOR NEGLIGENCE.

The liability of an engineer for negligence is similar to that of any other professional man. To render him liable it is not enough that there has been a less degree of skill than some other professional man might have shown. A fair average degree of skill is all that can be insisted upon (*Lamphier* v. *Phipos* (1838) 8 Car. & P. 475). If an engineer were so careless in the preparation of a tender that the cost of the works was grossly underestimated, he would probably be liable to pay damages, and he certainly could not recover his fees (*Moneypenny* v. *Hartland* (1826) 2 C. & P. 379). An engineer should be acquainted with any local bye-laws appertaining to the work in hand (*Monks* v. *Dillon* (1884) 12 L. R. Ir. 321). On the principle of *respondent superior*, an engineer is responsible for the acts or defaults of assistants employed by him (*Mackersy* v. *Ramsays* (1842) 9 C. & F. 818). The question 'To whom is the engineer liable for negligence?' depends upon the conditions of employment. If he is engineer in relation to a large contract, he is not liable for anything done by him in his capacity as arbitrator between the employer and the contractor; but he is liable for damage resulting from negligence in supervision, *e.g.*, failure to examine and test work before it is hidden from view (*Leicester Guardians* v. *Trollope* (1911) 75 J. P. 197). The contractor, however, could not sue the engineer for an error in the specifications on the basis of which he made his tender. Where, however, the 'quantities' are prepared by the engineer, and his fees for their preparation are paid by the contractor, it is conceived that he could be sued for damages resulting from an error in those quantities (*Bolt* v. *Thomas*, 'The Law Affecting Engineers,' p. 58). If an engineer order extras without authority, the contractor may possibly sue him for damages for breach of warranty of authority (*Randall* v. *Trimen* (1856) 18 C.B. 786). The amount of damages recoverable for negligence is to be measured by the loss which the plaintiff has suffered. In *Saunders* v. *Broadstairs Local Board* (1890) 2 H. B. C. 160, two engineers claimed fees for preparing surveys, obtaining tenders, and superintending the execution of a contract for certain drainage works. The board counterclaimed for negligence and were awarded 2,640*l.*, the amount overpaid to the contractor by reason of the negligence of the engineers in over-certifying the quantities; 2,400*l.* estimated cost of doing bad work over again; 240*l.* actual cost of repairs already done to defective work. Damages recovered by a workman against his employer for an accident might also be recovered from the engineer if it were shown that the accident was caused by the engineer's negligence (*Mosdell* v. *Mitchell*, 'Times,' January 20, 1891).

(10) RIGHTS, POWERS, AND DUTIES OF AN ENGINEER UNDER A CONTRACT FOR WORKS.

(i.) Generally.—Common forms of contract for large works usually set forth the powers, etc., of the engineer very clearly. The preparation of the contract is generally left to a lawyer, and the engineer should be on his guard against allowing a common printed form to be applied indiscriminately to the construction of works of a special nature. When difficulties arise it may be found that the common form does not provide for their elucidation.

(ii.) Specifications.—The contract should contain a clause providing that the employer will not be responsible for any mistakes or inaccuracies in the specifications which form part of the contract. Such a clause will, in the absence of fraud, afford him protection (*Pearson* v. *Dublin Corporation* (1907) A. C. 357). There should also be a clause calling the would-be contractor's attention to the fact that he must make surveys and borings for himself before making his tender. In that case, if unforeseen difficulties are met with the employer will not be responsible (*Thorn* v. *Mayor of London* (1876) L. R. 1 A.C. 120). Again, where a man undertakes to make *e.g.* sound hydraulic cylinders according to a specification, capable of withstanding a certain pressure, he takes upon himself the risk of the cylinders being able to withstand the named pressure when made according to the specification (*Hydraulic Co.* v. *Spencer* (1886) 2 T. L. R. 554). Carelessness in the preparation of a specification may involve the employer in added expense, for which the engineer may be liable (*Moneypenny* v. *Hartland* (1828) 2 C. & P. 378).

(iii.) Plans and Drawings.—These form part of the contract, and may, in the absence of a disclaiming clause, operate as a warranty that dimensions, measurements, etc., are correct. A clause disclaiming responsibility for accuracy should therefore be inserted in the contract. The engineer has no implied authority to alter plans and drawings so as to increase or lessen the burden imposed upon the contractor (*Cooper* v. *Langdon* (1841) 9 M. & W. 60). Delay in supplying the necessary plans and drawings may excuse the contractor from carrying out the work within the contract time (*Roberts* v. *Bury Commissioners* (1869) L. R. 5 C. P. 310). It is for the engineer who prepares them to see that they conform to local bye-laws (*Cubitt* v. *Smith* (1864) 11 L. T. 298). Plans and drawings made for the purpose of carrying out works are the property of the employer—not of the engineer (*Gibbon* v. *Pease* (1905) 1 K. B. 810). As to copyright in plans, see the Copyright Act, 1911, s. 5.

(iv.) Extras.—The duty of deciding what are 'extras' within the meaning of the contract is usually entrusted to the engineer. He has no implied authority to order extras (*Cooper* v. *Langdon* (1841) 9 M. & W. 60), although an agreement to work *to the satisfaction* of an engineer has been held to give him implied authority to order extras (*Robertson* v. *Jarvie* (1910) 45 S. L. R. 260). It has been held, however, that where the plaintiffs were employed by an architect (whose functions, for this purpose, correspond to those of an engineer) to supply door handles and door furniture for a building, and shortly before the delivery of the goods he informed the defendants, who were the builders, that the goods were being supplied by the plaintiffs, the defendants who used the goods in the building were liable to pay for them (*Ramsden* v. *Chessum* (1914) 78 J. P. 49). Extras should be authorised in the manner provided by the contract, which usually provides that all extras shall be ordered in writing (*Russell* v. *Saida Baudeira* (1862) 13 C. B. N. S. 149); but, in the case of a contract with a local authority, which must be under seal, the order for extras need not be under seal (*Williams* v. *Barmouth Urban Council* (1897) 77 L. T. 383). If a written certificate is rendered necessary by the contract, nothing else will suffice; but in a recent case a contractor proceeded with extra work as required by an engineer without any written order. On his claiming payment, an arbitrator found that the engineer was wrong and unreasonable, and that the work and materials required by him were not included in the contract. After much litigation the House of Lords eventually held that this decision was correct (*Brodie* v. *Cardiff Corporation* (1919) 120 L. T. 417). Although the whole scheme of works cannot be altered by virtue of the extra clause (*R.* v. *Peto*, 1 Y. & J. 37) power to *vary* the work will give the engineer authority to substitute one piece of machinery for another of which it is well known to be the mechanical equivalent (*Stevens* v. *Mewes & Davies*, Court of Appeal, June 7, 1910; Emden's 'Building Contracts,' Supplement 1911). The engineer should therefore see that he has power to *vary* the work. The engineer's decision as to what are extras may or may not be subject to revision in accordance with the arbitration clause. So far as the contractor is concerned, the fact that the engineer has given his final certificate (see *sub tit. Certificates, post*) may involve a final decision as to what is and what is not an extra (*Connor* v. *Belfast Water Commissioners* (1871) 5 L. R. Ir. C. L. 55). Power to extend the time for completion is generally given to the engineer. It may be that owing to the action of the Government acting under the Defence of the Realm Acts, the performance of a contract for works becomes illegal during the continuance of the War. In such a case it is conceived that no extension of time by the engineer will avail to keep the contract alive (see *Metropolitan Water Board* v. *Dick, Kerr & Co.*, 34 T. L. R. 1111).

(v.) Certificates.—It is the duty of an engineer in relation to a contract for large works to grant or withhold the certificates upon which the contractor is paid. 'Progress certificates' are given from time to time as the work proceeds. They generally authorise payment to the extent of 80 per cent. upon the contract value of the work done from time to time. The remaining 20 per cent. is kept back usually, as to 15 per cent. until the final certificate is granted and as to 5 per cent. until the end of some stated period after the final certificate. This 20 per cent. is called the retention money (see *West Yorkshire Bank Ltd.* v. *Isherwood Bros.* (1912) 28 T. L. R. 593). The 'final certificate' is granted when the work is finished to the satisfaction of the engineer, and the contractor can sue for nothing until it has been granted (*Wallace* v. *Brandon and Byshottles U.D.C.* (1903) 2 H. B. C. 392). In deciding as to certificates the engineer acts as an arbitrator, and his decisions cannot be called in question (*Wadsworth* v. *Smith* (1871) L. R. 6 Q.B. 332); nor can he be compelled, and is better advised not to give reasons for his decision (*Stevenson* v. *Watson* (1879) L. R. 4 C. P. D. 148). No action lies against him for negligence in relation to certificates (*ib.*) (but see the case of *Goddard* v. *Ferguson*, *infra*). In exercising his discretion he must act as an arbitrator between employer and contractor (*Chambers* v. *Goldthorpe* (1901) 1 K.B. 624). It may, however, be that the decision of the engineer as to a certificate is subject to the arbitration clause, which has been held to be the case in relation to the form of contract approved by the Royal Institute of British Architects (*Robins* v. *Goddard* (1905) 1 K.B. 294). A fraudulent agreement between the employer and the engineer would however affect the validity of a certificate (*Kellett* v. *New Mills U.D.C.* (1900) 2 H. B. C. 230). The certificate of the engineer may be made a condition precedent to the contractor's right of action against the employer. If so an action cannot be maintained unless there has been improper dealing between the engineer and the employer (*Eaglesham* v. *McMaster* (1920) 2 K. B. 169). The statement that an engineer is not liable for negligence in relation to a certificate does not appear to be supported by the case of *Goddard* v. *Ferguson* (referred to by Mr. Saxon Snell in a paper read by him at the Royal Institute

of British Architects, April 15, 1912). It was there held that an architect who grants a certificate which is successfully challenged by an employer in an action brought against him by a builder to recover the amount so certified to be due to him, is liable to repay to the employer the costs incurred by him in resisting the builder's claim. The Official Referee held the architect liable on the ground that when acting as agent for the building owner in granting certificates, he must be held responsible for the reasonable and probable consequences of giving a certificate subsequently held to be inaccurate or excessive. Certificates should always be given in writing in a formal manner. No engineer should pass any contract which does not contain a provision to this effect. As to when an engineer is disqualified from granting certificates, see paragraph ix., *infra*. An engineer has no right to delegate the power to grant a certificate to a subordinate, *e.g.* to the resident engineer (*Freeman & Sons* v. *Middleton Electric Traction Co.*, per Hamilton J., July 15, 1910; Court of Appeal, January, 1911; Emden's 'Building Contracts,' Supplement, 1911).

(vi.) Penalties and Bonuses.—The question whether the contractor must pay penalties or not depends almost entirely upon the engineer. Penalties are imposed if the work is not carried out in accordance with the provisions of the contract as to time. The fact that extras are ordered will excuse the contractor from compliance with the conditions as to time (*Dodd* v. *Churton* (1897) 1 Q.B. 562), but the jurisdiction of the engineer does not extend to deciding this point (*Gallivan* v. *Killarney Urban Council* (1912) 2 Ir. R. 356). To avoid complication, however, it is best to insert a clause in the contract giving the engineer power to extend the time. With regard to the penalty clause generally nice questions sometimes arise as to whether it is capable of enforcement. If it is unreasonable on the ground that the punishment is too severe, the Court may refuse to enforce it; and it is for this reason that the words 'the sums to be regarded as liquidated damages and not as a penalty' are usually inserted after the sum named. The breach of an engineering contract involves damage of so uncertain a nature that the courts will generally treat the sum which the parties themselves have named as liquidated damages. Penalties will not be imposed if (*a*) the delay was caused by the act or default of the employer (*Thornhill* v. *Neats* (1860) 8 C. B. N. S. 831); (*b*) if there is delay in setting out the site or in delivering plans (*Roberts* v. *Bury Improvement Commissioners* (1870) L. R. 5 C. P. 310). The fact that the contractor has been delayed by a strike of his workmen, however, affords no excuse for delay (*Budgett* v. *Rimington & Co.* (1890) 25 Q. B. D. 320), nor, apparently, is the employer to be held liable for the acts of third parties causing delay (*Porter* v. *Tottenham U.C.* (1915) 1 K. B. 776). While a penalty clause is usually optional, it is obligatory in contracts made with certain local authorities (see Public Health Act (1875) s. 174 (2)). A bonus clause is sometimes inserted by virtue of which a contractor is enabled so much extra for expedition. If a contract contains such a clause, and the engineer has power to extend the time, it seems that his power to extend must be exercised not to enable the contractor to earn the bonus but only to avoid penalties (*Ware* v. *Lyttelton Harbour Board* (1882) 1 N. Z.R. 191).

(vii.) Defects, Repairs, and Maintenance.—In contracts relating to the erection of machinery clauses should be inserted providing for any defects which appear either before or after the issue of the final certificate. A useful form of this clause will be found in the printed conditions of contract issued by the Institution of Electrical Engineers. Its importance will be recognised when it is pointed out that when it is absent the final certificate of the engineer may possibly bar any further claim by the employer (*Lord Bateman* v. *Thompson* (1875) 2 H. B. C. 23). The time for the remedy of defects should be prolonged as much as possible inasmuch as the very fact of there being a defects clause impliedly releases the contractor from liability for defects appearing after the stated time (*Sharp* v. *Great Western Railway Co.* (1841) 11 L. J. Ex. 17). The contractor can only be called upon to repair and maintain when compelled to do so by a repairing clause and a maintenance clause. The employer must give notice of want of repair. Maintenance should be provided for in cases where the machinery or work is of a special character which is best known to the contractor. In the absence of any clause relating to defects and maintenance, it does not follow that on payment of the full price the employer thereby waives all claim for damages for work improperly done. It is a question of fact having regard to all the circumstances of the case whether the settlement was final and complete.

(viii.) Subcontractors and Specialists.—Most modern contracts involve the employment of subcontractors or specialists. A clause should be inserted in the head contract prohibiting the employment of any subcontractor or specialist unless approved by the engineer. In the absence of such a clause, the contractor might, possibly, farm out portions of the work to all and sundry (*British Wagon Co.* v. *Lea* (1880) 5 Q. B. D. 149). The engineer, apparently, has no implied authority to employ subcontractors (*Cowan* v. *Goderich* (1859) 10 U. C. C. P. 87). It is often well to specify the names of manufacturers of the raw materials which are to be used in the body of the contract. In order to preserve his right to supervise the work of any subcontractor or specialist, the engineer should secure the insertion in the head contract of a clause providing that payments to subcontractors shall be made by the contractor only upon the certificates of the engineer. It is also well to secure the insertion of a clause to the effect that, in the event of the contractor becoming insolvent, the subcontractor or specialist may be paid directly by the employer. All responsibility for delay or negligence on the part of a subcontractor is generally, by a special clause, placed upon the contractor (see, generally, *Crittall* v. *L. C. C.* (1910) 75 J. P. 203; *Hampton* v. *Glamorgan County Council* (1916) 115 L. T. R. 426, and the case of *Ramsden* v. *Chessum*, cited, *supra*, s. (9) (v.) i.)).

(ix.) Whether the Employer's Engineer can act as Arbitrator in Relation to Disputes Arising under a Contract.—The position of the engineer in relation to a large contract has been rendered very difficult by certain recent decisions of the courts. In theory he is agent for the employer in the preparation of plans and specifications and in the supervision of the work, and he is arbitrator or *quasi* arbitrator between the employer and contractor in granting certificates, approving work done, granting extensions of time, etc. Sometimes he is made sole arbitrator to decide all disputes between the employer and the contractor, and a serious question has arisen in several recent cases as to how far a contractor can be forced to accept his decision whether in the matter of granting certificates, etc., or as arbitrator. In *Jackson* v. *Barry Railway Co.* (1893) 1 Ch. 238, it was held that the fact of the employer's engineer having expressed a view of the matter in dispute hostile to the contractor was not a sufficient justification for refusing to allow him to act as arbitrator in relation to that dispute. The Court of Appeal pointed out that the contractors had agreed to this form of reference, and what they relied on was the professional honour, practice, and intelligence of the engineer. There was nothing in the circumstances of the case to render it improbable that he would not arrive at an honest decision.

In *Ives* v. *Willans* (1894, 2 Ch. 478) the same result was arrived at, although in giving judgment Lord Justice Davey said: 'No doubt in a sense the engineer will be the judge of his own conduct, and no doubt that is a position which *prima facie* raises some surprise in a judicial mind; but that is the contract of the parties.' As already indicated later decisions appear to have practically altered the law, although the judges always took care to say that *Ives* v. *Willans* is still good law. The result of the recent cases may be thus summarised. A contractor will not be bound to submit to the arbitrament of the employer's engineer (*a*) if the matter in issue is an unseemly personal dispute raising a vindictive feeling between the engineer and the contractor, and the engineer has so strongly expressed his view that it amounts to a prejudgment (*Nuttall* v. *Manchester Corporation* (1893) 8 T. L. R. 513); (*b*) if the nature of the dispute is such that the cross-examination of the engineer is essential (*Freeman* v. *Chester R. D. C.* (1911) 1 K.B. 783); (*c*) if the matter in issue is something outside the original agreement, *e.g.*: a dispute as to whether the engineer and contractor had agreed to vary the original agreement (*Aird* v. *Bristol Corporation* (1913) A. C. 241); (*d*) if the conduct of the engineer himself is practically the only point in dispute (*Blackwell* v. *Derby Corporation* (1909) 7 J. P. 129). Finally, it was held in *Roberts* v. *Hickman* (1913) A. C. 229 that the grant of a certificate by an architect will not be a condition precedent to the builder's right to sue if, by writing letters to the employer, and allowing himself to be influenced by their views, the architect has disqualified himself from acting judicially although guilty of no fraud or improper conduct.

If the method of arbitration provided for in many existing forms of contract is declared to be impossible for any of the above reasons the only alternative is litigation, a method of settling disputes which employers, contractors, and engineers always seem to desire to avoid. What can be done to avoid such a calamity in relation to future contracts? The following courses are open. Insert a clause (*a*) referring all disputes to an arbitrator to be mutually agreed or to be nominated by the president of one of the Institutes (see, *e.g.*, the form approved by the Institution of Electrical Engineers, clause 47); or (*b*) referring disputes to a *named* arbitrator; or (*c*) refer disputes to the president of one of the Institutes whoever he may be. The first of these suggestions appears to offer the best practical solution of the difficulty. The writer, however, ventures to make the following suggestion which might possibly work in practice. Frame the arbitration clause so as to leave the decision of every question arising under the contract to the engineer but subject to a proviso that should it appear to the Court on an application to stay any action or proceeding brought in relation to the contract that the engineer is disqualified from acting as arbitrator the matters in dispute will be referred to an engineer to be agreed between the parties, or failing agreement to be nominated by the president of the Institution of Civil Engineers. Another alternative is suggested by Mr. E. J. Rimmer in his Arbitration Clause in 'Engineering Contracts' (Constable & Co.). It is that a proviso should be added to the arbitration clause stating that if any action is brought the defendant may either (*a*) have the action stayed or (*b*) have the matter referred to an independent arbitrator appointed in one or other of the manners above suggested.

(11) THE ENGINEER AS ARBITRATOR.*

(i.) Generally.—Engineers are frequently called upon to act as arbitrators to decide disputes of a technical nature wholly unconnected with any contract in which the engineer has been employed. Arbitrations are conducted in accordance with the provisions of the Arbitration Act, 1889. An arbitrator may be appointed (*a*) by the Court; (*b*) by the terms of the contract itself; or (*c*) by a person nominated for that purpose in the contract, *e.g.* the president of the Institution

* The Institute of Arbitrators, 10 Norfolk Street, London, W.C. 2, is always willing to suggest the names of qualified arbitrators with special technical knowledge. Reference to this body, therefore, tends to ensure that the arbitrator has the requisite technical knowledge as well as the legal knowledge and experience, which are so essential to the satisfactory conduct of an arbitration.

of Civil Engineers. As to appointment by the Court, this occasionally takes place when a prolonged scientific enquiry is necessary. A 'referee' of this kind may have power either to wholly dispose of the dispute or make an enquiry and report to the Court, in which latter case the Court itself gives the judgment after considering the report. As references of this kind are rare in practice they will not be further dealt with.

As a rule the engineer finds himself made arbitrator pursuant to the arbitration clause in an agreement. Any dispute arising under any contract may thus be referred, and the parties will as a general rule be bound to proceed to arbitration for the purpose of settling a dispute instead of bringing an action at law. Where a contract contains an arbitration clause, if one party commences an action, the other may apply to the Court to stay the action pending a reference, and the action will generally be stayed, unless there is some good reason for not allowing the arbitration to proceed. For instance a contractor alleged that he had been induced by fraudulent representations as to the nature of the soil to enter into a particular sewerage contract, and brought an action for fraudulent misrepresentation. It was held that such an action ought not to be sent to arbitration (*Monro* v. *Bognor Urban District Council* (1915) 84 L. J. K. B. 1091). But the Court will stay an action, and allow an arbitration to proceed, although the question at issue is one which might be more suitably tried in a court of law—*e.g.* the construction of a contract (*Metropolitan Tunnel, etc.* v. *London Electric Ry.* (1926) 1 Ch. 371). (See also par. 9 (ix.), *supra.*)

(ii.) Who may be Arbitrator.—Any person upon whom the parties agree may act as arbitrator. Thus if in a contract with a local authority it is specified that the borough engineer shall be arbitrator there is no objection to his so acting, and the contractor can be compelled to accept his award (*Ives* v. *Willins*, *supra*, 2 Ch. 478). That is the broad rule, but the Court, as has been shown, always has power to refuse to enforce the arbitration clause in a case where it is obvious that the arbitrator ought not to act owing to bias, etc. Frequently the clause provides for the appointment of an arbitrator by each party with power to the arbitrators in case of differences to appoint an umpire.* When this is done the umpire and arbitrators generally find it convenient to sit together to decide the case.

(iii.) Proceedings before the Arbitrator.—Witnesses must be sworn in the usual way. Due notice must be given to either party of the time when it is proposed to hold the sitting. In a case of great complexity it is well to have a preliminary sitting in order to require the parties to formulate the points in difference between them. By this means the issues may be considerably narrowed. The arbitrator should hear both sides, who may be represented by solicitor or counsel. He must never hold private communication with one party on the subject matter of the reference. He has no power to examine witnesses in the absence of the parties. An arbitrator who takes evidence in the absence of, and without notice to, a party, is guilty of legal misconduct, for which his award may be set aside (*In re O'Connor*, 88 L. J. K. B. 1242; *Ramsden* v. *Jacobs* (1922) 1 K. B. 640). It is for the arbitrator to decide every question whether of law or fact. He may, however, consult a solicitor or, for that matter, any other expert on legal points. Indeed the writer was recently concerned in a case in which, with the consent of the parties, the arbitrator had his solicitor sitting by his side. He should take full notes of the evidence, unless, as is frequently the case, the parties agree to have a shorthand note.

(iv.) The Award.—If the case is complex, the engineer is well advised to consult his solicitor as to the form of the award. The following are the features of a valid award, which should be in writing. (*a*) *It must not exceed the submission.* Thus if the question submitted was whether the stone used for building a dam was according to specification, the arbitrator would have no power to award that the stone used was better than as specified and that the employer must pay for it. (*b*) *It must extend to all matters in dispute.* If several distinct questions are referred and the arbitrator omits to decide upon any one of them, the whole award is bad. If in the case mentioned he were asked to decide (i.) was the stone as specified; (ii.) was it suitable for the purpose, he would have to decide both questions. (*c*) *It must be certain.* The award must be so framed that its meaning is clear to the parties; but according to a legal maxim, that is certain which is capable of being rendered certain. Thus to award that A. and B. shall pay a debt in the proportion in which A. and B. hold shares in a ship is a sufficiently definite award (*Watson* v. *Watson* (1671) Sty. 28). (*d*) *It must be final.* The award must peremptorily state the arbitrator's finding. A mere expression of opinion that A. ought to pay B. such sum as C. thinks proper would not be a final award. Finally (*e*) *it must not be impossible, unreasonable, inconsistent*, or *illegal.* An award which directed that one party should do something illegal, *e.g.* trespass upon the land of another, would be invalid.

(v.) Time for Making an Award.—Formerly an award had to be made within three months of the date of the submission. Now, however, by virtue of the Arbitration Act, 1934, s. 6 (3), an award may be made at any time. But observe that an arbitrator who is *dilatory* may be removed by the Court; so that he should do his work with all reasonable dispatch.

* An engineer who is appointed by one party to a dispute, the other party appointing another arbitrator, will usually find it advisable to nominate a Fellow of the Institute of Arbitrators with special knowledge of the subject in dispute as the umpire.

(vi.) The Fees of an Arbitrator.—The arbitrator should arrange his fee beforehand. It is best fixed at so much *per diem* for the hearing. If no preliminary arrangement is made, he is entitled to charge what is fair and reasonable, and he can keep back his award until the fees are paid (*Ponsford* v. *Swain*, J. & H. 433). If the arbitrators keep back his award on such a ground, the Court may order that the award be delivered, on payment of the amount of fees claimed into Court. The fees can then be 'taxed' by a taxing master. If they are excessive, the 'excess' is paid out to the party paying in; and the balance to the arbitrator, who, by the way, has the right to be present at the taxation. When deciding in the award as to costs he should state who is to pay his fees; but he may insist upon their being paid by the party who takes up the award. He should not reveal his decision until after these formalities have been observed. Sometimes the *quantum* of an arbitrator's fees is left to the decision of a taxing master. On such a taxation, if the evidence goes to show that, in the opinion of persons in the same profession as the arbitrator, that his charges are fair and reasonable, the taxing master must allow them. In *Mason* v. *Lovatt* (1907, 23 T. L. R. 486) a quantity surveyor was allowed to charge 527*l*. 10*s*. for a reference which lasted 22 days, the arbitrator subsequently taking 13 days to consider his opinion. In *Llandrindod Wells Water Co.* v. *Hawksley* (1904, 20 T. L. R. 241) the fees of an umpire and two arbitrators all being engineers were allowed at 476*l*. 12*s*., in respect of a reference which lasted 2 days. The arbitrator should state how his fees are made up.

(vii.) Stating a Case for the Opinion of the Court.—Where a specific question is referred to an arbitrator, and he decides it, the fact that his decision is erroneous in point of law does not make the award bad on its face so as to admit of its being set aside (*In re King and Duveen* (1913) 2 K. B. 32); nor will the mere fact that the dispute involves questions of law induce the Court to stay a reference to arbitration (*Rowe* v. *Grossley* (1913) 108 L. T. 11). But where a point of law arises during a reference, the arbitrator, if he does not care to decide it, may state a case for the opinion of the Court (Arbitration Act, 1889, s. 19), or the Court may compel him to state a case (*ib.*). He can also make his award in the form of a special case, leaving it to the Court to decide how the judgment shall be entered. Refusal to state a case may constitute misconduct on the part of an arbitrator (*Czarnikow* v. *Roth Schmidt & Co.* (1922) 38 T. L. R. 595).

(viii.) Miscellaneous Powers of an Arbitrator.—By virtue of the Arbitration Act, 1934, an arbitrator may order security for costs; 'discovery of documents'; the examination of witnesses at home or abroad (where (*e.g.*) he is not able to take such examination); and the detention (for safe custody) of property in dispute. He may also order samples to be taken or observations or experiments to be made with a view to obtaining information or evidence.

(ix.) Costs of a Reference.—On the question of costs, and as to the form of that part of his award which relates to costs, an arbitrator should consult his solicitor, because (*a*) highly technical questions arise with regard to costs and their taxation which no layman can be expected to understand, and (*b*) it is desirable that in this matter an arbitrator should observe as nearly as possible the principles which are recognised in courts of justice. Again, the defendant in the proceedings may have preferred a counter-claim in which he may have been successful wholly or in part. This further complicates the question of costs. It may be observed that there is no objection to an arbitrator employing a lawyer to advise him in the matter of costs or with reference to any other question which arises in a reference. The importance of taking this course is that a layman has not, and in the nature of things cannot have, the same mental outlook as a court of justice in dealing with the question of costs. Let a recent example suffice. An arbitrator made an award of £200, but as the plaintiff had claimed £1,200 and only succeeded as to £200, he made each side pay its own costs. In the result the plaintiff got less than nothing at all, as his costs far exceeded £200. Such a decision as to costs was, from a lawyer's view-point, entirely wrong. The arbitrator wholly overlooked the fact that the plaintiff was compelled to sue to recover anything at all. In any event, and whether a solicitor is employed or not, the question of costs should be carefully considered, as the expenses of a reference are often wholly out of proportion to the sum in dispute. In litigation the general rule is 'costs follow the event'—an application of the maxim *væ victis*. Unless the submission contains some special term as to costs, the arbitrator has full power to decide who is to pay them, and he should exercise the power; otherwise the parties may be put to the expense of applying to him for an order as to costs. (See Arbitration Act, 1934, s. 11 (2.). He may award costs to be taxed 'as between solicitor and client'—which means that the successful party is nearly indemnified—or he may award costs to be taxed as between litigants in the ordinary way. He may also, in his discretion, award a fixed sum for costs (Arbitration Act, 1889, Schedule I. (i)), or he may declare that each party shall pay his own costs. In deciding whether to make a defendant pay costs, the arbitrator should (it is submitted) consider the nature of any offer made before the proceedings were commenced. Thus supposing a contractor claimed 5,000*l*. and the building owner made a firm offer of 4,000*l*. which was refused. After hearing the evidence, the arbitrator awards 4,000*l*. or less. In such a case he would be justified in disallowing the contractor any costs. An arbitrator can only make a successful plaintiff pay costs in exceptional circumstances as when (*e.g.*) it appears that although successful he should not have prosecuted his claim. It was held, however, in a case arising under the Small Holdings Act, 1908, the arbitrator in the exercise of his powers under that Act had wider powers in the matter of costs than a High Court judge (*Gray* v. *Baron Ashburton*, 115 L. T. R. 729).

(12) NOTES ON SALE AND PURCHASE OF MACHINERY.

The question which most frequently arises on the sale of machinery, motor cars, etc., is what is the warranty of fitness? Sometimes, of course, there is an express written warranty, but in the absence of that the matter is regulated by section 14 of the Sale of Goods Act, 1893, which provides (in effect) that there is no implied warranty or condition as to the quality or fitness for any particular purpose of goods supplied under a contract of sale, except (1) where the buyer expressly makes known the purpose for which the goods are required so as to show that the buyer relies on the seller's skill or judgment and the goods are of a description which it is in the course of the seller's business to supply (whether he be the manufacturer or not) there is an implied condition that the goods shall be reasonably fit for such purpose; provided that in the case of the sale of a specified article under its patent or other trade name, there is no implied condition as to its fitness for any particular purpose; (2) where the goods are bought by description from a seller who deals in goods of that description (whether he be the manufacturer or not) there is an implied condition that the goods shall be of merchantable quality; provided that if the buyer has examined the goods there shall be no implied condition as regards defects which such examination ought to have revealed; (3) an implied warranty or condition as to quality or fitness for a particular purpose may be annexed by the usage of trade; (4) an express warranty or condition does not negative a warranty or condition implied by the Sale of Goods Act unless inconsistent therewith. The result of these provisions is that in certain cases the vendor is made liable for latent defects, that is to say, for defects which would not be discoverable on an ordinary examination of the article. Sometimes a contract for the sale of machinery contains provisions for payment of the price by instalments after production of the certificate of the engineer that such instalments are due and payable. It was held in a Scotch case (*Howden* v. *Powell Duffryn Steam Coal Co.* (1912), S. C. 920, Ct. of Sess.) that where, in such circumstances, part of the machinery was rejected, but the manufacturers refused to accept the rejection, the production of the engineer's certificate was not a condition precedent to the right to recover payment.

In the case of an engine which is attached to the freehold, a question may arise, on a sale, as to when the property passes. In *Underwood Ltd.* v. *Burgh Castle Brick and Cement Syndicate* (1922, 1 K. B. 343), a horizontal condensing engine was sold at a price free on rail, London. It was bolted to and embedded in a flooring of concrete. Before it could be delivered on rail it had to be detached and dismantled. The sellers detached it, but in loading it on a truck they damaged it by accident so that the buyers refused to accept it. In an action by the sellers for goods bargained and sold it was held that the property in the engine had not passed to the buyers, inasmuch as the sellers had failed to do something necessary to put it in a deliverable state. Consequently the loss fell on the sellers and not on the buyers.

* For Diameters advancing by 'Tenths' shift the decimal point one place to the left for Circumferences, and two places to the left for Areas.

EXAMPLE.—What is the circumference and the area of a circle whose diameter is 1·7 (i.e. 17 tenths)?
Circumference = 5·3407 Area = 2·2698.

SQUARES—CUBES—ROOTS—RECIPROCALS.

SQUARES—CUBES—ROOTS—RECIPROCALS.

TABLE OF SQUARES, CUBES, SQUARE AND CUBE ROOTS, AND RECIPROCALS, OF NUMBERS FROM 1 TO 1,000.

Number.	Squares.	Cubes.	$\sqrt{\text{Roots.}}$	$\sqrt[3]{\text{Roots.}}$	Reciprocals.	Number.	Squares.	Cubes.	$\sqrt{\text{Roots.}}$	$\sqrt[3]{\text{Roots.}}$	Reciprocals.

Characteristic of log. of number containing one or more integral figs. is one *less* than the number of integral figs., and is positive.

Characteristic of log. of a number wholly decimal is one *more* than number of noughts at commencement of decimal, and is negative.

To multiply by logs., add logs., and find corresponding numbers.

To divide by logs.. subtract logs., and find corresponding numbers.

To extract the root, divide log by index, and find corresponding numbers.

To obtain any power, multiply log. by index, and find corresponding numbers.

Use of Differences.

Ex. 1.—Find the log. of 32685.
Difference (D) for 326=133 log. 32680=4·514282†
133×5= 665*
4·5143485

In all cases last fig. of * must be set one beyond last fig. of †.

Ex. 2.—Find number corresponding to log. 3·774743
Given log. . . . . 3·774743
Nearest log. in table . . 3·774736=log. 5953
Divide by Difference (D) 73)7 01
Required number =5953·1

Hyperbolic or Natural Logarithms.

Hyp. log. = Common log. × 2·30258509. Common log. = Hyp. log. × ·43429448.

DESCRIPTIVE SECTIONS

SECTION II

PART II

Powers.

FROUDE HYDRAULIC DYNAMOMETER.

(Heenan and Froude Limited, Worcester, England.)

This dynamometer is standardised in the following chief types :—

1. *Types D.P.X., D.P.Y. and D.P.Y.D.*, in small and medium sizes up to 4,000 B.H.P. for testing the B.H.P. of engines such as those of motor cycles, motor cars and commercial road vehicles, high speed Diesel engines, etc.

2. *Types S.A. and F.A.*, in medium and large sizes for dealing with comparatively slow speed prime movers such as land and marine Diesels, oil, gas, and steam engines, slow speed or geared turbines, etc. Machines have already been constructed up to 60,000 B.H.P. in a single unit but a wide range of smaller sizes is available.

3. *Type F.V.*, which operates on somewhat similar principles to those of the F.A. and S.A. types, and which is employed for high-speed high-powered engines such as aircraft engines and turbines up to 5,000 B.H.P.

In operation the engine upon test is directly coupled to the dynamometer shaft and transmits power to a rotor revolving inside a casing, through which water is circulated to provide the

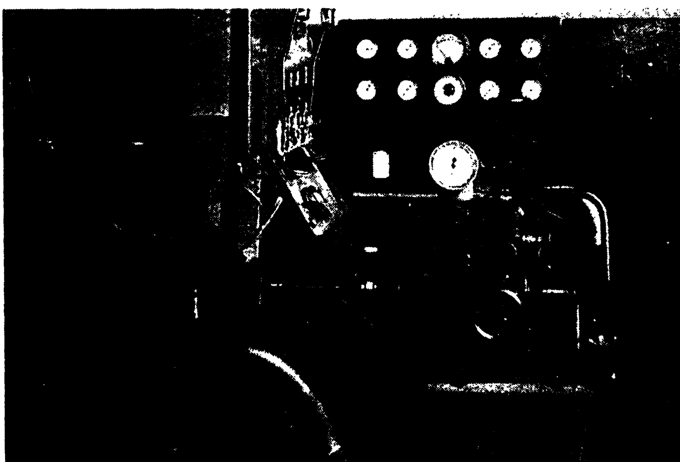

FIG. 1.

hydraulic resistance and simultaneously to carry away the heat generated by destruction of power. In the standard D.P.X. type dynamometer the load imposed is controlled by varying the position of metal sluice plates which mask the rotor to a greater or lesser extent; this operation can be carried out while running by the operation of a single handwheel. The dynamometer casing is supported upon anti-friction trunnion bearings so that it is free to oscillate under the influence of the torque absorbed, and is only restrained from doing so by the torque weighing gear connected to a balance arm bolted to the casing. By this means all forces resisting rotation of the dynamometer shaft are caused to react upon the weighing gear, which thus gives scientifically accurate readings in all conditions of load and speed.

The D.P.Y. and D.P.Y.D. are basically similar to the D.P.X. type, but a different form of weighing gear is used, adapted for heavier torques, and the D.P.Y.D. in particular is of higher capacity. Special high-speed models are available for testing such prime movers as gas turbines, steam turbines, etc.

In the S.A. and F.A. Types, similar power absorbing elements are employed, but the method of road control is different. Instead of the rotor cups always running full of water as in the D.P.X. type, the volume of water contained therein is varied by the operation of a valve and the D.P.X. type sluice-plates are not employed. This valve is of a special design which gives the dynamometer automatic self-governing properties such that should the speed of the engine increase, the

dynamometer load also increases. The contrary effect takes place upon a decrease in speed, and these features are of great assistance in keeping steady the speed of the engine upon test and minimising 'hunting,' often caused previously by the usual slight variations of engine output.

These large machines are also provided with a Torque Meter which eliminates the long balance arm and heavy weights previously necessary; it consists of a system which allows the torque to be accurately measured by small weights and greatly reduces the test shop floor space required by the dynamometer.

All 'Froude' Dynamometers have an extremely wide range of power and speed and one size can thus cater for a large variety of engines. Except in the smaller sizes, they incorporate means for adjusting the centres of the dynamometer shaft for ease in alignment of the engine, and in all cases they form self-contained units complete with their own bedplates and torque measurement gear, only requiring to be coupled to the engine and supplied with water to be in readiness for tests.

HEENAN-DYNAMATIC DYNAMOMETERS.

The Heenan-Dynamatic Dynamometer originated in America, where it has been installed on a wide scale, and has now come into extensive use in this country. It comprises a steel rotor, having no electrical windings or connections, running inside a plain steel housing, the latter being surrounded by a fixed coil. Rotation of the rotor inside the field set up by the coil causes the generation of eddy currents and thus absorbs power, the load being regulated by varying the excitation of the coil. The machine can be supplied in a range of capacities up to considerable powers. In all models the control gear is of electronic type, made in various standard forms, which provide definite technical advantages and make the Dynamometer particularly easy to operate.

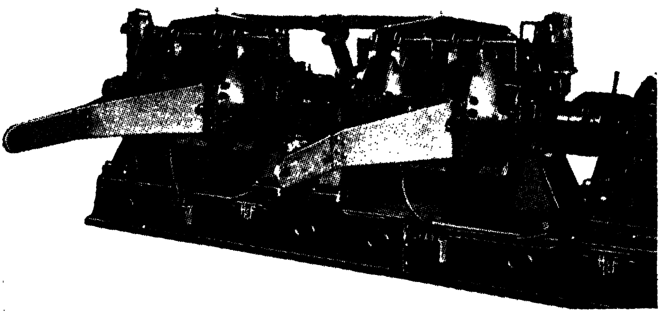

FIG. 2.

Being inherently reversible, it is specially useful to makers of marine engines and is now standard practice for testing aircraft engines. Special models are available for testing contra-rotation engines, an example of such a machine being illustrated in fig. 2. Very high speeds are catered for by special designs; machines have already been made for 2,400 B.H.P. at 24,000 r.p.m.

HEENAN ELECTRIC DYNAMOMETERS.

The Heenan D.C. Electric Dynamometers incorporate special control gear and are normally provided with torque weighing mechanism constructed on Froude principles and giving the same strict accuracy of reading. Models are available for production testing, research testing, or a combination of both; they can be made automatic or semi-automatic, and recover the engine power in the form of electric current, in addition to the benefit of motoring the engine for running-in or research.

A.C. Electric Dynamometers are also available for certain duties, particularly as Motoring Dynamometers for ascertaining the B.H.P. absorbed at various speeds by the mechanisms on test.

FROUDE AIRCRAFT ENGINE TESTING PLANT.

The Froude Wind Tunnel Testing Plant has been installed by most of the chief aircraft engine builders and by many foreign governments, and consists of a Dynamometer for testing the B.H.P. of the engine, acting in conjunction with a centrifugal or axial-flow fan which is employed when testing air-cooled engines for directing the necessary cooling air-blast over the engine. This plant is usually supplied complete in all details including wind tunnel itself with fan and driving motor, dynamometer of suitable type and capacity, cardan shaft between dynamometer and engine, universal engine cradle, and the necessary instruments and accessories such as petrol and

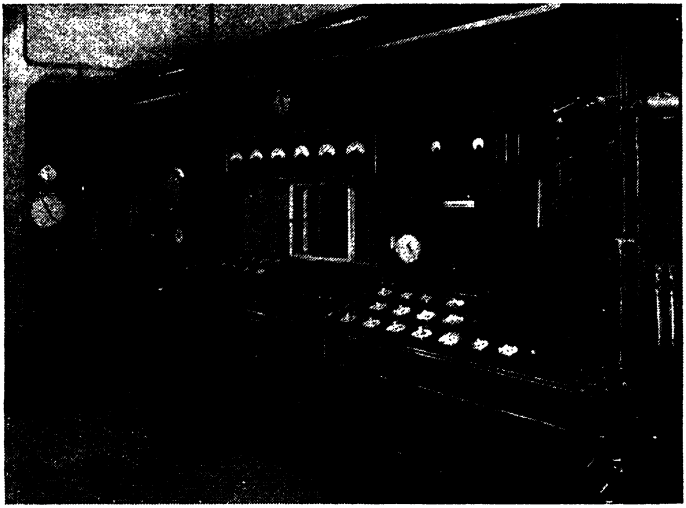

FIG. 3.

oil systems, flowmeters, gauges, etc. One plant of this type can deal with a large range of engines, whether air-cooled or liquid-cooled, and is equally suitable for production or research testing.

Modern wind tunnel plants are usually arranged for remote control. All measuring devices, controls, instruments, gauges, etc. are mounted conveniently to the testers; the control room is silenced, so that most of the testers' time is spent in a fresh, cool atmosphere free from exhaust fumes, heat and noise. Special precautions are taken to keep the control room free from petrol fumes, thus minimising fire risks. A view of the control panel of a typical research plant is given in fig. 3.

HEENAN HANGAR STAND.

The Heenan Hangar Stand is a simpler form of aircraft engine test plant than the Froude Wind Tunnel Plant described above, and is in extensive use for testing overhauled and repaired engines. In most cases the Cable-Suspended type is installed, as it provides a more flexible method of mounting the engine; in some installations, however, a rigid structure is employed, often with rubber mountings interposed between engine and structure. These Hangar Stands do not incorporate a dynamometer, reliance being placed upon a special 'test fan' or airscrew fitted on the engine shaft, to absorb a certain power at any given speed, and at the same time to provide an air blast for cooling air-cooled engines.

The accuracy of these Hangar Stands is not to be compared with the Froude Wind Tunnel Testing Plant, but it is often considered sufficient for dealing with engines which have been overhauled, as opposed to new engines tested in an engine factory.

THE CROSBY INDICATOR.

(Crosby Valve & Engineering Co., Ltd., Crosby Works, Ealing Road, Wembley.)

This indicator has been designed for use with either steam, gas or oil engines. Fig. 1 shows the Crosby Indicator as ordinarily made, having a drum 1¼ ins. in diameter, this being the correct size for high-speed work and answering equally well for low speeds.

The special feature in the indicator is the use of a double-coil spiral spring, very carefully calibrated; this form of spring enables the strains to which it is subjected to be transmitted from the centre of the piston through a ball-and-socket joint. Each spring is made of a single piece of wire wound from the middle into a double coil, the ends of which are screwed into a head with four wings having spirally drilled holes to receive and hold them securely in place. Adjustment is made by screwing the spring in or out of this head until it is exactly of the right strength, when it is firmly brazed.

Fig. 2 shows the Crosby New No. 2 Indicator, whilst fig. 3 shows a sectional view of the same indicator. This has the spring mounted outside the cylinder, where it is easily detached and replaced, and where it is removed from any effect of heat—a very necessary precaution when the indicator is used with superheated steam, or on gas engines. Another novel feature in this indicator is the shape of the piston. It is in form the central zone of a sphere, an arrangement which

practically eliminates cylinder friction. The piston is connected to the pencil mechanism by a rod terminating in a ball-and-socket joint in the centre of the piston. The position of the pencil lever on the drum can be altered by screwing the spring up or down and locking it in place.

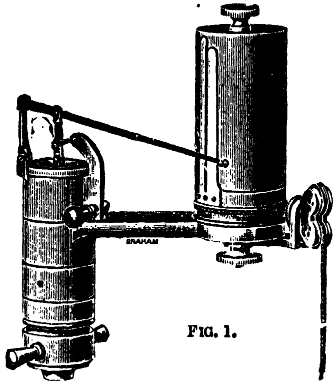

FIG. 1.

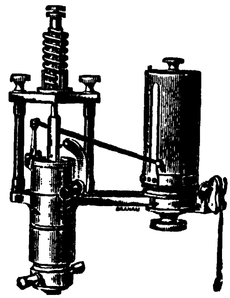

FIG. 2.

For the purpose of making the indicator of the utmost value to engineers, the Crosby New 'Continuous Drum' has been designed, and this apparatus makes it possible to obtain a series of diagrams on a roll of paper. The latest form has a novel arrangement, allowing the period

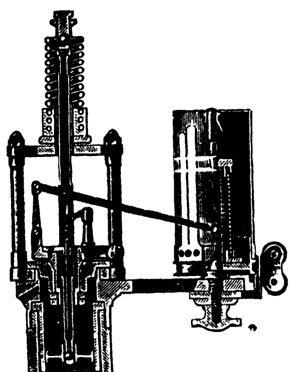

FIG. 3.

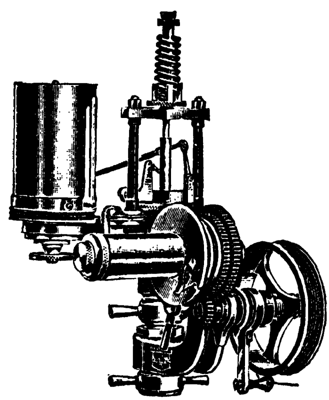

FIG. 4.

between each diagram to be altered at will; the diagrams can be taken close together or farther apart as desired, and the roll supplied is 12 ft. long. Such an apparatus is of great value in ascertaining variations of load in electrical tests, and in connection with rolling and winding engines.

Another useful device, which saves having a reducing apparatus added to an engine, is the Crosby 'Reducing Wheel.' This gives a perfectly correct reduction of the stroke of any engine to the stroke of the indicator drum, and it is connected directly to the indicator and mounted on the indicator cock. The arrangement is portable and can be used on any engine.

The latest pattern includes a detent device which enables the indicator to be stopped to put on a fresh card without disconnecting the reducing wheel from the engine crosshead, see fig. 4.

SECTION IV

Acoustics, Vibration and Noise.

Sound Abatement and Acoustical Treatment.

(Fibreglass Limited, Ravenhead, St. Helens, Lancs.)

The aim in modern buildings is, generally speaking, to omit almost everything that has been found unnecessary to hold the structure together and enable it to withstand the ravages of the weather, etc. Coinciding with this demand for minimum structural requirements there has been a great increase in the use of mechanical appliances, and this extended use of mechanism has forced us, more than ever before, to confront the problem of noise prevention.

The buildings being erected to-day offer little resistance to the transmission of sound from without, and the plasters and similar materials in use provide little absorption within.

The manufacturers of 'Fibreglass' offer a remedy in the form of a quilt (slabs and loose wool) and state that they have successfully developed their material to fill to some considerable extent the rôle previously occupied by solid structures.

They do not claim that the modern light structure, even when provided with insulation, offers the same resistance to sound transmission as that provided by the solid, massive structures of the older types of building. They do state, however, and point to the rapidly increasing use of their material in support of their claim, that 'Fibreglass' materials contribute largely to the 'comfortable' conditions experienced in the modern type of building where it is applied.

It is extensively used for floor insulation, and for this purpose is laid along the joists under the floor with battens between. Its function is to act as a cushion to take up sound vibrations, or, in other words, to break the continuity of hard rigid materials.

The quilt consists of long, flexible glass fibres encased in treated kraft paper or scrim cloth and stitched with thread to form a strong and durable quilt. 'Fibreglass' is chemically inactive, incombustible and odourless. It does not attract moisture and will not rot. Of great importance in building work is the fact that it offers no sustenance to vermin. Light and Medium Quilt is made up in rolls 1 yard wide by 27 yards long, and Thick Quilt in rolls 1 yard wide by 13½ yards long. Light Quilt is ¾ in. thick when uncompressed, Medium Quilt 1 in. thick when uncompressed, Thick Quilt 1½ in. thick when uncompressed.

'Fibreglass' has also been developed by the manufacturers for the acoustical treatment of speech halls, cinemas, studios, etc. For this purpose the material is made up in the form of panels consisting of a wooden framework enclosing 'Fibreglass' quilt faced with materials suitable to meet the requirements of interior decorations. For studio work it is supplied in the form of mattresses with 'Fibreglass' encased in wire mesh.

'Fibreglass' possesses very high sound absorption values and the following figures have been obtained from tests recently conducted by the National Physical Laboratory:

Reverberation absorption coefficients at various frequencies.

'Fibreglass' 1 in. thick in mats nailed on	250	500	1,000	2,000
battens 3 ins. by ¾ in. fixed to wall surface	0·75	0·90	0·90	0·95

SECTION IX.

PART II.

Roofing Materials—Painting.

'ROK' ROOFING.

(*D. Anderson & Son, Ltd., Stretford, Manchester.*)

'Rok' roofing forms a permanent and easily applied roof covering. Only the highest grade of felt fibre is used in its manufacture. This is saturated with an elastic water-proofing compound which does not dry out or evaporate in any climate, as it contains no oils, or volatile matter. The coating on the surface is a permanent one, composed of a natural bitumen of very high melting point. There is nothing of an organic nature in either the saturating or coating compound. It is acid and alkali proof and not affected by white ants. It is suitable for pitched, flat, or circular ('Belfast') roofs, and for reinforced concrete roofs it will be found to make a thoroughly water-tight job.

Rain water from roofs covered with it can be used for domestic purposes.

Being an excellent non-conductor, it ensures an even temperature, and is therefore an ideal roofing for hot climates.

It is laid on close jointed boarding, which should not be less than ¾ in. thick, either plain edged or tongued and grooved. The purlins or rafters should be so spaced that there is no appreciable spring in the boarding.

It may be fixed either longitudinally from gable to gable, or vertically from eaves to eaves. It is, however, considered advisable to lay it crosswise to the boarding. The joints should be formed with at least 2 ins. overlap, being stuck together with 'Rok' cement and carefully nailed with tacks not more than 2 ins. apart placed in the centre of the seams. The heads of the tacks where exposed and the outside of the seams should be dressed with 'Rok' cement.

'Rok' roofing is supplied in rolls of 72 ft. by 3 ft. wide, in the following grades:—

½-ply average weight,	50 lb.	per roll	2-ply average weight,	80 lb.	per roll
1-ply „	60	„	3-ply „	100	„

(The above weights do not include the nails and cement.)

The prices including the supply of special galvanised broad-headed nails and liquid cement or fixing will be quoted by manufacturers on application.

Each roll, if carefully laid, should cover 200 sq. ft.

The manufacturers will undertake to carry out the fixing if desired.

'Rok' roofing may also be used on concrete, fixed with special 'Rok' mastic, and it is advisable to write the manufacturers for full directions as to the method of applying.

It may also be used for covering flats and gutters. In this case it is recommended to use two layers, the first layer being tacked to the boarding, and the top layer stuck to the under one with 'Rok' mastic. In this way no nail heads are exposed. Flashings to walls, round lights, etc., may be made in the material.

'FLEXTILE' ROOFING.

'Flextile' Roofing is a new variety of roofing specially produced for use on dwelling-houses and other buildings where a more attractive appearance is desired than that of the usual bitumen roofings. It is made of similar materials to 'Rok,' and is of the same high quality in every respect, but the surface is covered with crushed minerals, in either red or green natural unfading colours. These minerals are firmly embedded in the surface of this roofing, which is quite as attractive in appearance as are slates or tiles, with the advantage that there is no possibility of breaking or cracking, and that no wind or water can ever penetrate to the interior. 'Flextile' Roofing is, in fact, storm-proof.

Supplied in rolls 12 yds. by 1 yd. sufficient to cover 100 sq. ft. Weight 80 lb. per 100 sq. ft., *i.e.* about ⅘ lb. per sq. ft. Price including nails and cement, red or green, quoted on application.

RUBEROID ROOFING.

(*The Ruberoid Co. Ltd.*, 28 *Commonwealth House*, 1-19 *New Oxford St.*, *W.C.* 1.)

Ruberoid is a bituminous roofing manufactured in sheet form and suitable for use on flat-pitched or curved roofs of wood or concrete, and has been so employed extensively for fifty years.

Complete roofing contracts are carried out by the firm's Contract Departments in any part of the British Isles and, through their agents, in any part of the world.

Ruberoid is light, flexible, waterproof, resistant to the effects of acid and alkaline fumes and sea air, and unaffected by extremes of heat and cold. It has excellent heat insulating properties and is consequently very suitable for use in tropical countries.

Standard Ruberoid roofing is made in three weights, and is grey. Where colour is required Ruberoid Red Roofing can be employed; or, alternatively, Ruberoid Mineral-Surfaced Roofing, which has a surface of natural crushed slate. It is supplied in three colours: Thatched Brown, Westmorland Slate Green and Natural Bangor Steel Blue.

Where an extra high degree of fire resistance is required, Ruberoid Astos Roofing, with an asbestos base, is available.

Ruberoid roofs are of two main types:—

(1) Roofs consisting of a single layer of Ruberoid.

(2) Built-up roofs consisting of two or more layers of Ruberoid underlay bedded together on the site with a finishing surface appropriate to the service required on the roof.

For small roofs consisting of a single layer of Ruberoid which can be fixed easily by unskilled labour, Ruberoid is supplied in rolls 36 in. wide, complete with accessories.

Ruberoid Built-up Roofs can be laid with several alternative finishes:—

(*a*) Standard Ruberoid.
(*b*) Ruberoid Astos Asbestos Roofing
(*c*) Mineral-surfaced Ruberoid.
(*d*) Gravel.
(*e*) Ruberdal tiles or Ruco Ruberoid.

Ruberdal is a Ruberoid Built-up roof finished with tiles. It is particularly suitable for verandahs and terraces subjected to foot or wheeled traffic.

Ruco Ruberoid is a Ruberoid Built-up roof with a surface of Ruco Mastic Asphalt and is suitable for foot and wheeled traffic, chairs, etc.

The Ruberoid steel roof deck is a rigid covering equally suitable for flat or sloping roofs and can be employed over purlins or joists spaced at maximum centres of 8 ft. The steel units are light and the complete roof only weighs 4½ lb. per square foot.

Insulation is included in this system of roofing to reduce transference of heat. The insulating material is usually provided in a half-inch layer of building board between the steel deck units and the weatherproofing. In this position it is isolated from moisture and can, therefore, function at its full efficiency. The weatherproofing usually consists of a single layer of Ruberoid bonded to the insulation on pitched roofs, while on flats the Ruberoid built-up system of two layers is employed.

Ruberoid steel roof deck can be accommodated to meet any spacing of joists or purlins up to 8 ft. No definite or exact spacing of supporting members is necessary.

SECTION X

Mortars—Concretes—Cements—Plasters—Placing Concrete.

THE CROCKATT SIMPLEX POLISHER FOR TERRAZZO FLOORS.

(*W. Crockatt & Sons, Ltd.*, 62 *Darnley Street, Glasgow, S.* 1.)

To meet the demand for increased speed of polishing Terrazzo, Mosaic, 'Cullamix' and similar floors, the Crockatt Major Double Disc polisher has been produced.

The latest electric model is illustrated and, as will be seen, has a direct worm drive from the motor to the two polishing spindles.

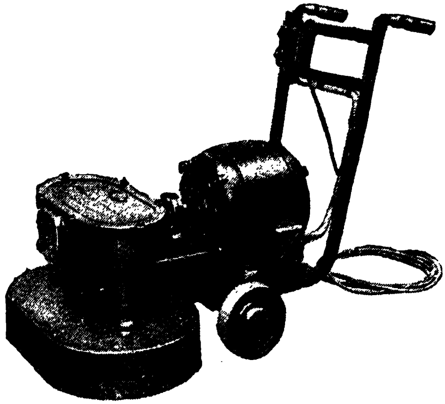
Each spindle carries three polishing blocks, flexibly mounted and arranged on a clover leaf form so that the two polishing heads intermesh while revolving. The result is that the machine is particularly easy to operate, as the action of the two heads make it practically self-propelling along the floor.

The machine polishes a strip 22 ins. wide, and will give any desired finish, depending on the grit and grade of blocks used.

It is, we are informed, particularly successful on 'Cullamix,' which is a very hard material and now largely used for swimming pools, as well as ordinary flooring work.

The machine is fitted with ball bearings throughout; the gearing runs in an oil bath and lubrication of the spindles, etc., is by grease gun.

An efficient splash guard is fitted and is easily removable so as to give access to the polishing heads. The polishing blocks are standard size and can be supplied in a variety of grits and grades to suit various materials.



The motor fitted as standard is single-phase, direct starting, but three-phase or direct current can be fitted if required.

If preferred, a petrol engine can be fitted so that the polisher can be used in buildings before the electric supply is laid on or is otherwise not available.

The machine, as well as the other models made, can be fitted with a flexible shaft and wall polishing attachment which is very simply brought into use when required.

Where space is limited—as for example on landings, vestibules, bathrooms, etc., the appropriate machine is the Minor Double Disc Type, which is very compact, light and easily handled, and can be operated from any electric light plug or socket.

Should it be preferred to use pre-cast tiles, the same firm makes polishing machines for these, the polishing being done on the same principle as already described.

These machines, known as the Jenny Lind pattern, are also used for polishing marble slabs, which can be cut into suitable pieces on the carborundum marble sawing machines made by Messrs. Crockatt. The polishing machines are arranged for wall mounting and for direct electric or belt drive.

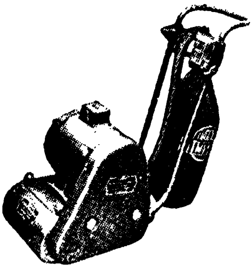
The Sawing Machines are also in use for sawing fireclay goods, such as sinks, etc., where a modification of standard sizes is required. They are also employed in the cutting of wall or floor tiles to special shapes and sizes.

THE CROCKATT-SIMPLEX FLOOR SANDING MACHINE.

(W. Crockatt & Sons, Ltd., 64 Darnley Street, Glasgow, S.1.)

The base of this sander is made of aluminium as are all the components except where they must be of iron or steel because of wear.

The sander has an aluminium drum which is covered with sponge rubber and has a simple method of securing the sand-paper. The length of the drum is 10 in. and the diameter 6¾ in. The drum pressure can be adjusted gradually from a very heavy cut to a light skim, this adjustment being by means of a lever close to the tubular handle. The switch is conveniently placed on the



handle and is so mounted that it cannot be accidentally switched on, that is to say, the switch must be pulled up to put it on, and not pushed down, the latter arrangement being the cause of occasional accidents.

The motor is 1½ h.p. single-phase 230 volts 50 cycles, as standard, and gives a drum speed of 1,500 r.p.m., but three phase or direct current motors can be supplied. Full particulars of current supply are necessary. As electric power is not always available, an air-cooled petrol engine can be fitted, this being easily replaced by an electric motor if desired.

The drive is by means of Vee belts. The reason for adopting Vee belts rather than chain, is that it is found by experience that the chain is apt to cause markings on the floor, particularly when this has to be highly polished.

The fan is mounted in the base as a complete unit and gives a very effective suction, the air and dust being discharged into an easily removable bag mounted at the end of a copper pipe.

Ball bearings are fitted wherever practicable.

The machine is a first-class job as to efficiency, workmanship and appearance.

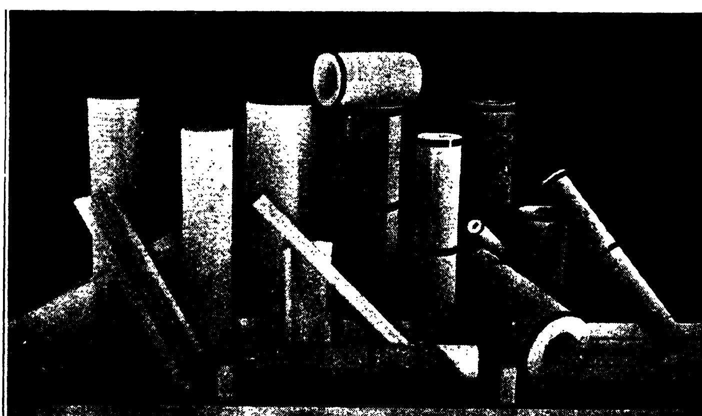
SECTION XI

Clays and Allied Products used by Engineers.

Heat Insulating Materials.

(The Chemical and Insulating Co., Ltd., Darlington.)

Darlington 85 per cent. Magnesia Coverings.—Among modern high grade boiler coverings those composed of magnesia take a leading place. The coverings, sheets, slabs and bricks manufactured by the Chemical and Insulating Co., Ltd., of Darlington, are composed of 85 per cent. of pure carbonate of magnesia which is manufactured by the firm by the Pattinson process. While the micro-cellular structure of magnesia forms an ideal insulating substance, further strength is obtained by the intermixture with it of 15 per cent. of best quality asbestos fibre, which binds the magnesia and gives a resultant compound possessing unusual strength and tenacity. The Darlington works of the firm are a modern factory which have been laid out for the production of magnesia coverings in all forms, and are equipped with the latest specially designed machinery for such work. Where large heated surfaces are to be insulated, skilled application of coverings is required for best results and the company undertakes the application of its materials in most countries of the world. The insulation of steam piping, etc., may readily be undertaken however with unskilled labour by the use of Darlington 85 per cent. Magnesia Moulded Sectional Covering, which is supplied in standard thicknesses of 1 in., 1½ in., and 2 ins., and for pipes from ½-in. to 8-in. bore. This covering can be supplied with an outer wrapping of canvas, asbestos paper or roofing felt, together with neat steel strips, one per foot length of covering, for securing the insulation in place.



For insulation of boilers, engine-room casings, drying cupboards, turbines and sundry other applications, Darlington 85 per cent. Magnesia Slabs are supplied in standard sizes of 36 ins. by 6 ins., by any thickness from 1 in. to 4 ins. Other sizes can also be supplied. Where semi-portable insulation is required these slabs are wrapped in asbestos paper.

For insulation of irregular surfaces and for general use, Darlington 85 per cent. Magnesia Plastic is available. This is a powder, delivered in half-hundredweight bags, which is supplied ready for mixing with clear water to the consistency of mortar, for application to the surface to be insulated, which must, however, be heated. One ton of Darlington 85 per cent. Magnesia Plastic will cover about 2,400 sq. ft. surface when applied to a thickness of 1 in.

Dextramite' High Temperature Coverings.—For temperatures above 600° F. the firm specially recommends 'Dextramite' high temperature coverings, which it has been shown by National Physical Laboratory tests will not char or disintegrate when subjected to temperatures up to about 1,600° C. They are manufactured in forms generally similar to the Darlington 85 per cent. magnesia coverings, and also in brick form for insulating blast furnaces, gas mains, retorts and boiler casings, etc. The bricks have a crushing stress of 3½ tons per sq. ft.

The illustration on p. 1102 shows a variety of the products of the firm, which is in a position to advise and to supply expert information and materials for all classes of insulation work.

'FIBREGLASS' FOR HEAT INSULATION.

(Fibreglass Limited, Ravenhead, St. Helens, Lancs.)

'Fibreglass,' although a comparatively new insulating material, is rapidly being adopted over the complete steam pressure and temperature ranges in modern engineering practice.

The material is stated to consist entirely of glass of a high melting point; it withstands high temperatures without exhibiting any defects.

'Fibreglass' for heat insulation is made up in a variety of forms and consists essentially of a mass of very fine glass fibres lying closely together and enclosing within their structure millions of minute air cells, which, aided by the characteristic sheen of the silken fibres, offer a determined resistance to the passage of heat.

Very high insulating efficiencies are claimed by the manufacturers, and the following are figures determined by the National Physical Laboratory:

	Insulating Efficiency.		
	At 50 lb. per sq. in. gauge.	At 100 lb. per sq. in. gauge.	At 200 lb. per sq. in. gauge.
'Fibreglass' 1 in. thick	87·9 per cent.	88·9 per cent.	88·9 per cent.

The following are the heat losses based on the N.P.L. figures from a 4½-in. O.D. steam pipe with steam at 370° F. and an atmospheric temperature of 70° F.:

	Loss. B.Th.U.'s per sq. ft. of pipe surface. Per hour.
'Fibreglass' 0·5 in. thick	174
" 1·0 " "	110
" 1·5 ins. "	84
" 2·0 " "	69
" 2·5 " "	60
" 3·0 " "	53

'Fibreglass' for heat insulation is made up in the form of strips for convenient winding round steam pipes and in the form of rigid sections. It can also be provided in sheets or mattresses for placing on boilers or other large surfaces. The outer finish may be sheet steel, hard-setting cement, asbestos cloth, canvas or waterproof felt, depending on requirements.

It will be readily understood that the material, being composed entirely of the chemically inert substance—glass—is extremely durable. Durability tests over a period of eight years are reported by the manufacturers. The tests have been conducted on small coasting vessels where the insulation has been more often awash than otherwise. Notwithstanding the excessive treatment, it is stated that the material after ten years continues to give high insulating values and shows no signs of deterioration. The long fibres of which it is made up cling together with remarkable tenacity. It would appear that this is due partly to the semi-woven nature of the threads and partly to the high coefficient of the friction between glass surfaces. It is this property which provides 'Fibreglass' with its remarkable resistance to vibration and other influences tending to cause disintegration.

The material is, of course, quite incombustible, and of particular interest is the fact that it offers absolutely no sustenance to vermin.

The manufacturers guarantee the material up to 900° F., but state that a series of tests have shown that it will withstand temperatures considerably higher, and is, in fact, in use on installations at 1150° F. without showing the slightest sign of disintegration or fusion.

STEEL TUBULAR SCAFFOLDING.

(Burton's Patent.)

(The London & Midland Steel Scaffolding Co., Ltd., Burwood House, Caxton Street, London, S.W. 1.)

Tubular steel scaffolding has now almost entirely superseded the old wooden poles. The advantages of steel are outstanding as compared with timber. From a structural point of view it is safer; the depreciation is negligible, risk of fire is eliminated, and the cost of erection in the saving of time and men is very considerable.

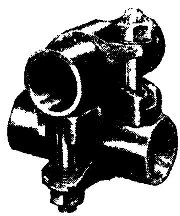

FIG. 1.

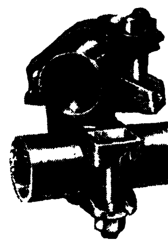

FIG. 2.

BURTON'S PATENT DOUBLE COUPLER (Fig. 1) is used for coupling upright tubes to horizontal tubes. Its features are great strength and load carrying capacity, and the speed with which it can be securely fixed or released. It is a one-piece coupler, no loose parts to get lost. The erection of scaffolding with this 'Quickgrip' coupler is simplicity itself.

BURTON'S PATENT SWIVEL COUPLER (Fig. 2) for coupling bracing tubes to strengthen scaffold.

BURTON'S PATENT PUTLOG COUPLER (Fig. 3). This coupler for fixing putlogs or transoms to horizontal tubes is very simple to secure. There are no projections interfering with the wood scaffolding boards and all wobbling or rocking is eliminated.

BURTON'S PATENT SPLIT JOINT PIN (Fig. 4). Half a turn of this bolt firmly secures two tubes together end to end.

BURTON'S BALL BEARING STEEL CASTORS are specially made for all types of mobile scaffolds. They are fitted with solid steel wheels or with solid rubber tyres and with or without a screw jack.

All the foregoing fittings are specially made for use with standard 1½ in. internal, 1$\frac{29}{32}$ in. external diameter tube. They are also made in 1 in. and 3 in.

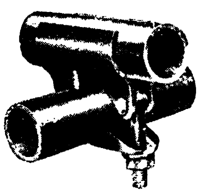

FIG. 3.

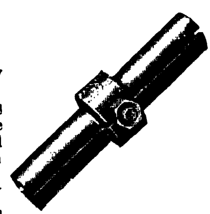

FIG. 4.

In addition to scaffolding the Burton's patent system lends itself to manifold uses, such as making heavy and light racks for storage purposes, temporary bridges, framework for huts, stands and launching platforms, diving stages and playing field equipment; in fact, it has supplanted the use of timber in many notable ways.

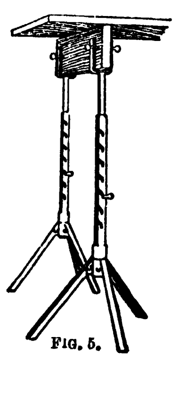

FIG. 5.

STEEL PROPS OR SHORES.

(Burton's Patents.)

These are used for centring floors, shuttering, etc., and have a positive adjustment by a very strong square thread pressure screw. No spanners or jacks are needed.

BURTON'S PATENT SPLIT HEADS

(Fig. 5). 'The Little Gem' Revolving Fork Head for interior scaffolds, for plasterers and decorators. To take one or two boards, with folding legs, or can be supplied with shoes for outside work on soft ground. No rachets or pegs to engage or bolts tighten, and positive adjustment not dependent on friction. Supplied in four sizes: 1 ft. 3 in. to 1 ft. 9 in. to reach 7 ft. to 8 ft; 2 ft. to 3 ft. to reach 8 ft. to 10 ft; 3 ft. 6 in. to 5 ft. 6 in. to reach 9 ft. to 12 ft.; 5 ft. 9 in. to 9 ft. to reach 12 ft. to 15 ft.

SECTION XVIII

PART VI

Water Supply.

Automatic Control Equipment for Water Softening Plant and Filters.

(*Filtrators, Ltd.*, 92 *Seymour Place, London, W.* 1.)

A typical example of the effectiveness of the automatic control of water softening plant is the complete control of the regeneration by brine of the zeolite bed of a base exchange water softener. In a plant of this type the only manual operation which has to be carried out in connection with its normal running is the replenishment of salt in the saturator at approximately 10-day intervals. In addition to the incorporation of this gear in new installations, existing manually controlled plants can be readily modernised by the fitting of automatic control equipment. The control system, which is extremely simple in respect of both lay-out and individual components, consists of an automatic control unit mounted on or near the softening or filtration plant. Each element of this unit is connected to its respective hydro-valve or operating ram by a $\frac{3}{16}$-in. copper pipe, generally as shown in figs. 1 and 2.

▬▬ Controlled power water.	——— 80 volt D.C. circuit.
- - - Uncontrolled power water.	- - - - 230/40 volt mains supply.

Automatic Control Units.—Two main types of controller are in service, the smaller being used mainly for the automatic control of filters and single-unit softeners, whilst the larger is used for large softeners or multiple unit filters and softeners. Basically, the controller consists of a revolving drum directly driven by means of a fractional h.p. electric motor through appropriate gearing. The drum, which is fitted with a series of adjustable cams makes one revolution in the time required or regenerating a softener, for performing any other complete process. The regeneration period for a typical softening operation occupies approximately one hour after each

complete softening cycle. Immediately below the cam drum is a relay block containing a number of relay valves, each being operated by the appropriate drum cam through the medium of a valve plunger. Additionally, any relay valve can be operated independently by hand control, if required, through the medium of a hand lever and the valve plunger.

Hydraulically Operated Valves.—The hydro-valves which are an essential feature of the automatic control system are well known for their smooth working and the long life which is obtainable from their seatings. As a result of the smooth working of these non-shock valves, water hammer in the pipes is entirely non-existent. For the automatic operation of gate valves, when these are incorporated in a system, servo action is provided by means of hydraulically operated double-acting rams. As a general rule pipes up to 3-in. diameter are fitted with hydro-valves, whilst pipes of 4-in. diameter and over have ram operated gate valves. If required for any special reason,

▬▬ Controlled power water. ——— 80 volt D.C. circuit.

······ Uncontrolled power water. - - - - 320/40 volt mains supply.

however, ram operated valves can be fitted to pipes down to 2-in. diameter. Apart from the electricity supply for operation of the motor the only other power required for automatic control is water pressure at 25 to 30 lb. per sq. in. Where, however, an air supply is more readily available than water pressure, this is equally suitable for use as the operating medium.

Typical Systems.—Two typical automatic control systems are shown diagrammatically in figs. 1 and 2, the former showing a base exchange softener system and the latter a pressure filter system. In the case of the softener system the controller is started by an electrical contact in the water meter M, making the circuit from the rectifier X in the electrical panel to the solenoid S on the automatic control unit. The energising of this solenoid causes it to operate a mercury switch which closes the main circuit to the control unit motor. Rotation of the control unit drum, which throughout the softening cycle had been stationary holding inlet and outlet hydro-valves A and B open, then commences and the regeneration process is in progress. The complete and correct sequence of shutting down the softener, backflushing, brine injection, rinsing and recommencing the softening operation is then carried out accurately and without any attention

whatsoever. The backwashing operations for the filter system, fig. 2, are carried out in a similar manner. In this case, however, the only hydro-valve incorporated is used to control the air inlet, all the other valves being controlled by double-acting rams. The making of the 80-volt circuit to the automatic controller is effected by a contact in the differential pressure gauge, G, which measures the loss of head through the bed of filter media. The development and supply of this simple automatic control system by Filtrators, Ltd., has the effect of providing an efficient method of control for water treatment plant. The firm is able to supply technical booklets which describe the equipment.

(*Reprinted from ' Water and Water Engineering '*).

In addition to the above plant, Filtrators Ltd. manufacture Filtrol base exchange softening plant, lime soda softening plant, using their special stabilisation process and acceleration methods, pressure and rapid gravity filtration plant, iron and manganese removal plant, water de-ionisation plant, chlorinating equipment, effluent treatment plant, condensate de-oiling plant (electrical process), continuous blowdown and heat recovery plant, and all types of dosing gear for dealing with every water treatment problem.

Waste Water Detection.

(*The Palatine Engineering Co., Ltd., Hawthorne Road, Bootle, nr. Liverpool.*)

The detection of invisible leakages between the reservoir and the consumer is usually done by meters of the ' Deacon ' type, similar to fig. 1. A large recording meter is fixed on the main

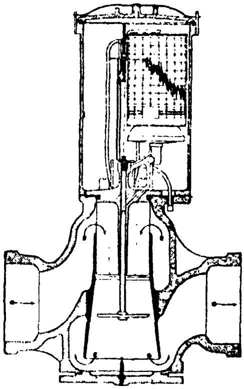

Fig. 1.

at the reservoir. The supplied area is divided into districts of about 2,000 inhabitants and arranged so that the whole supply comes from one direction, and passes through a Deacon meter. Fig. 2 is a plan of the area showing valves.

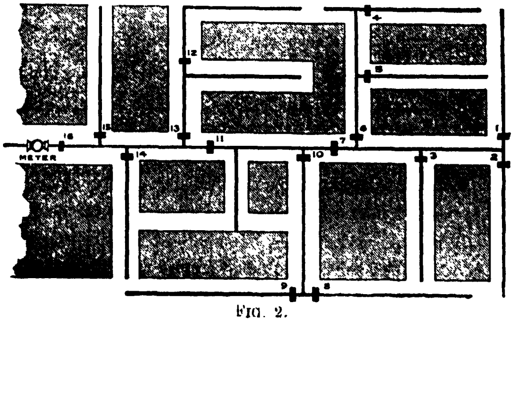

Fig. 2.

A typical chart for twenty-four hours in an uncontrolled district is shown in fig. 3. The minimum flow during the night is 2,000 gallons per hour (represented by the shaded portion), or 48,000 gallons per day. In the absence of night supplies for trade purposes, this water is leaking through defects. The water used (represented by the cross-hatched portion) is 29,775 gallons making a total supply of 77,775 gallons per day.

To locate this waste a chart is fitted in which the time scale is multiplied by four. During the night the inspector proceeds to the end of the district and closes No. 1 valve, and the other valves in succession, at about 15-minute intervals, noting the time and the location of the valve

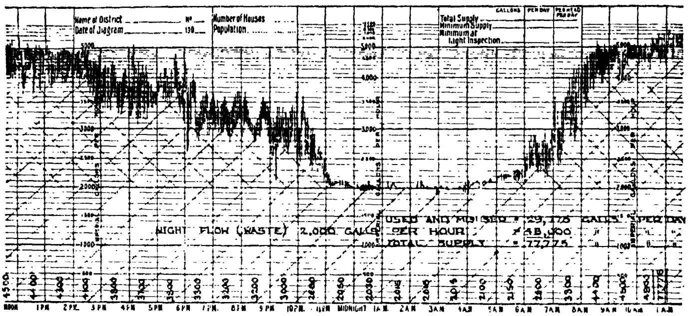

FIG. 3.

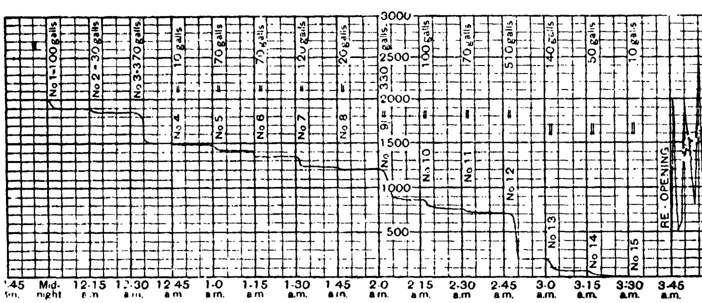

FIG. 4.

The result is shown in fig. 4, the rate of flow in each portion before isolating being clearly recorded. There is an indication of large defects in portions supplied through valves Nos. 3, 9, and 12. These are afterwards traced by a form of stethoscope and examination of fittings. In some of the areas where this system is carried out the consumption, in gallons, per head, per day, is:—Bath, 21; Birkenhead, 20·75; Bristol, 24·12; Cambridge, 23·2; Chesterfield, 16·0; Weston-Super-Mare, 22·1; Halifax, 17·74; South Staffs Waterworks Company, 15·13; Wakefield, 19·68. Trade requirements are measured through separate meters and are not included in these figures.

Filtration.

THE 'PULSOMETER' FILTER.

(The Pulsometer Engineering Co., Ltd., Nine Elms Iron Works, Reading.)

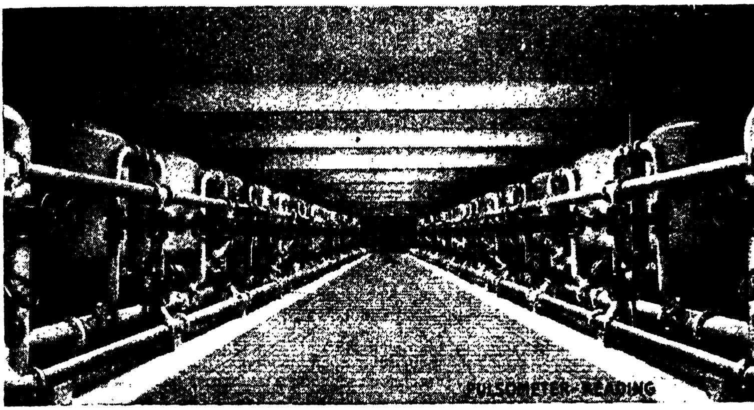
Filtration is effected by passing water under pressure through special carefully graded filtering media.

Arrangements are made so that cleansing can be carried out thoroughly and systematically.

Dual purpose nozzles fitted on the collecting system in the filter offer very little frictional resistance during filtration; a factor which contributes largely to low running costs.

The cleansing process is effected by compressed air forced back through the nozzles and agitating the bed. A reverse flow of water then carries all dirt in the filter over a skimming tundish and then to waste. The design of the nozzles is such that it is impossible to carry on the process of agitating and washing simultaneously, without mutual interference ; a low wash water consumption thereby being obtained.

An alternative method of agitating the filter bed is by use of steam.



Where steam at 40 lb. per sq. in. is not available for entraining air for filter bed cleansing, compressed air is usually provided by means of one of their ' Hydrair ' Motorless Air Compressors. This operates hydraulically and the risk of mechanical breakdown of moving parts or contamination of the water by leaking oil, as from a mechanically operated compressor, is therefore eliminated.

Automatic chemical dosing gear is installed for coagulation *p*H recording and control.

The illustration shows *one* bay of a recent pressure purification plant arranged to treat between six and eight million gallons of peaty water daily, producing a filtrate which fulfills all the requirements of a high grade drinking water for a town's supply.

The filters can be built to withstand any pressure and are made vertical or horizontal to suit accommodation and other conditions on site.

SECTION XIX

PART II

Hydraulic Transmission of Power.

Variable Speed Drive.

(Keelavite Rotary Pumps and Motors Ltd., Allesley, Coventry.)

This is a positive hydraulic drive in which an oil pump is operated by the prime mover and an oil motor transmits the power to the driven mechanism. By varying the respective capacities per revolution of the pump and/or hydraulic motor, complete control is obtained of both the speed and output torque of the hydraulic motor.

The pump and motor units are similar in construction and are in fact frequently identical. Where the oil motor is required to operate at approximately the same maximum torque throughout its speed range, it can be of fixed capacity; speed control from zero to maximum is then obtained by varying the capacity of the pump. If, on the other hand, it be required to exert a maximum horsepower which is constant over a substantial portion of the total speed range, so that as the speed falls the output torque must rise, then it is necessary to vary the capacity of the hydraulic motor over the corresponding portion of the speed range while keeping the capacity of the pump fixed. By means of a combined control of the capacities of pump and motor, any required relationship may be obtained between the speed and the available torque.

The Keelavite unit illustrated (fig. 1, p. 1111) is a standard model suitable for working pressures up to 1,000 lbs. per sq. in. The flow of oil from the inlet to the outlet port is controlled by the volume swept in the working chamber (1), by the blades of the rotor (2). This is driven by or drives the rotor housing (3), according to whether the unit is functioning as a pump or as a motor; the blades are a sliding fit in the slots in the rotor housing, and the capacity of the unit per revolution is proportional to the length of blade projecting from the rotor housing. The rotor is located axially by means of the locating rotor bearing (4), so that when the non-rotating rotor centre (5) is moved axially by means of the rack and pinion capacity control (6) the blades are carried with it, and so are enabled to maintain a fine clearance sealing fit over their end faces with the face (7) of the rotor centre, which constitutes one end wall of the working chamber. The rotor and the rotor housing both receive radial location from the non-locating rotor housing bearing (8), through which the rotor slides when the capacity is varied, while the rotor housing is located by the locating rotor housing bearing (9) so that its face, which constitutes the other fixed end wall of the working chamber, is flush with the face of the abutment end plate (10). This completes the circumferential seal round the outside of the rotor housing, and also maintains a face seal with one end face of the abutment (11), the other end face of which seals with the abutment bearing housing (12). The circumference of the abutment seals with the abutment bore in the casing, and also with the arc AA of the rotor centre. Owing to the fact that this arc AA is longer than the arc BB limiting the abutment recesses, it will be seen that at all times the abutment maintains a seal between the inlet and outlet ports. The abutment recesses enable the blades to pass from the outlet to the inlet ports when not pumping, the rotor and abutment being timed together by the timing gears (13), (14), so as to permit the free passage of the blades through the recesses. Owing to the fact that the blades completely enter the abutment recesses before the abutment commences to seal again at the end of the arc AA, adjacent to the delivery port, the blades are able to displace exactly their own volume of oil out of the abutment recesses, so that there is no net change in displacement on the delivery side of the pump. As a result, the output is entirely free from pulsation, a feature the importance of which cannot be over-estimated.

Radial hydraulic balance is ensured in the case of the rotor by the fact that the leak paths on its inside and outside diameters are similar, while in the case of the abutment the patented Keelavite system of balancing recesses and passages ensures that there is a perfect symmetry of the radial pressure forces. Axial balance of the abutment is ensured because it is located with equal clearance on either face, while the rotor is kept in axial balance by maintaining the casing pressure by means of an automatic valve at the mean of the inlet and outlet pressures. As a result, there are no loads at all on the abutment bearings, and only the torque reaction load on the rotor bearings.

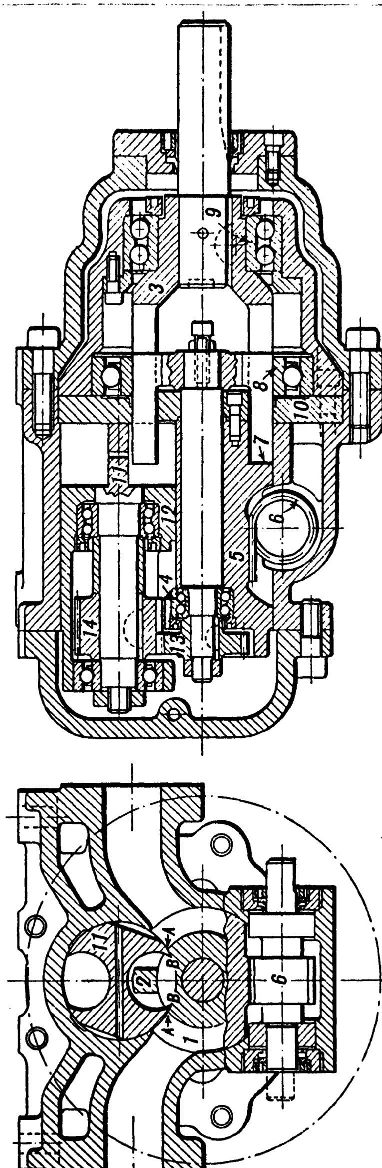


FIG. 1.—Arrangement of Keelavite Variable Capacity Pump.

In large units where even the torque reaction constitutes an undesirable bearing load, a twin abutment design is utilised with four ports, two inlet and two outlet, ensuring a complete symmetry of pressure conditions around the rotor; as a result, there are no bearing loads at all on the rotor bearings, the rotor itself being in pure torsion, as in the case of an electric motor.

Typical performance curves are shown in figs. 2 and 3 taken from standard units of 5 cub. ins. capacity. These indicate very clearly the very high mechanical efficiencies attained with Keelavite pumps and motors. In addition, the high starting torque and very flat characteristic over a wide speed range should be noted. As a general guide it can be stated that power efficiencies of the order of 85 to 90 % per unit can be relied upon under reasonable conditions at maximum power without need for the units to be of uneconomic size. In the case of rotary drives, the maximum pressures consistent with this order of efficiency range from 400 to 1,500 lb. per sq. in.,

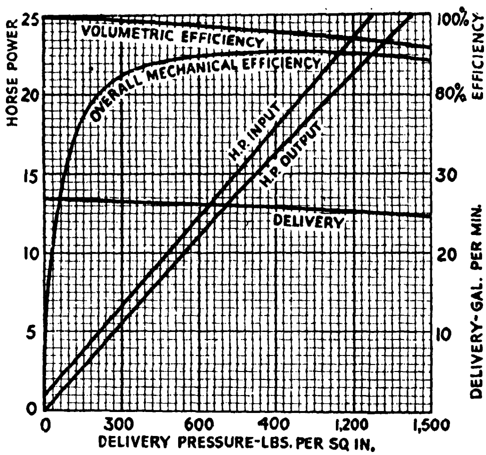

FIG. 2.—Performance Curves of Keelavite Pump.

Capacity: 5·0 cub. ins. per revolution.
Oil Viscosity: 150 secs. Redwood No. 1.

increasing with the horse power under consideration. When a hydraulic pump only is required to operate a receiver of high volumetric efficiency (such as a hydraulic press cylinder) even the smaller units can be operated at pressures up to 1,500 lb. per sq. in., and in certain cases up to 2,250 lb. per sq. in. without undue sacrifice in efficiency.

Owing to the fact that there is an absolute absence of frictional contact in the mechanism of the Keelavite units, their working life, provided that the oil is kept clean, is dependent only upon that of the ball bearings employed. These are kept well within their catalogue rating, and accordingly it can be stated that the life of the units is of indefinite duration.

In addition to pumps and rotary hydraulic motors, Keelavite standard equipment includes a comprehensive range of valve gear, which is intended for use in connection with rotary drives and also for use in conjunction with the pumps to control various types of reciprocating movements in which hydraulic rams are employed in place of rotary motors.

Thus, piston type directional valves are available, which for example may be interposed between a pump and rotary hydraulic motor in order to obtain reversal of the direction of rotation of the hydraulic motor. This type of valve is manufactured so that when required it can also be used to stop the motor, in which case it has three control positions corresponding to forward, neutral, and reverse; while the valve itself may be either directly, manually, or mechanically controlled, or may be controlled by a hydraulic pilot valve which is in turn suitable for solenoid operation where electrical control is desirable.

In order to avoid overloading on hydraulic circuits when sudden changes in speed or load take place, or when starting, stopping, or reversing, the Keelavite piston controlled balanced poppet type relief valve has been specially designed to secure instantaneous response together

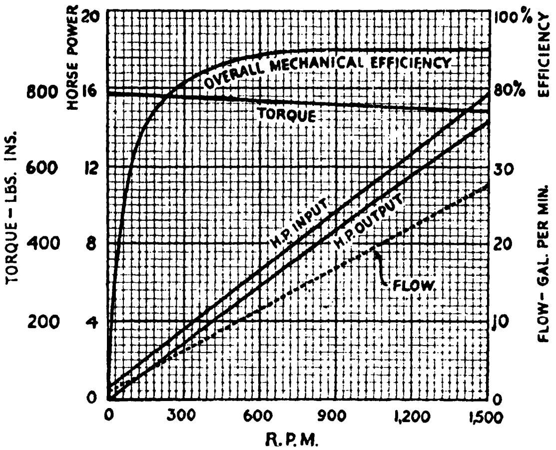

FIG. 3.—Performance Curves of Keelavite Motor.

Capacity: 5·0 cub. ins. per revolution.
Oil viscosity: 150 secs. Redwood No. 1.
Input pressure: 1,000 lbs. per sq. in.

with a quiet performance even when passing large flows. This valve has the further advantage that the pressure setting is independent of the rate of flow through the valve so that peak loads can be accurately controlled under all conditions; while in addition it is suitable for operating as a remote controlled by-passing valve when required.

In addition the Keelavite range of valve gear comprises various types of flow control valves arranged to give accurately controlled flows independent of the operating pressure in question from any suitable source of pressure fluid, such as a fixed capacity pump or hydraulic accumulator. Such flow control equipment is of the greatest value where it is required to obtain consistent speed control over a wide range, particularly at low operating speeds of hydraulic rams or motors.

THE 'VSG' MARK III. VARIABLE DELIVERY PRESSURE PUMP.

(*Vickers-Armstrongs Ltd.* (*Variable Speed Gear Dept.*), *Vickers House, Westminster, S.W. 1.*)

This pump is of the 'Williams-Janney' or horizontal piston type. Fig. 1 (p. 1114) shows a vertical section through the latest design (arranged for lever control).

The 'mainshaft' is driven in one direction, and carries a rotating block or 'cylinder barrel' mounted on it by a universal joint and which is free to move axially.

This 'cylinder barrel' contains cylinders bored parallel with the mainshaft, having ports of reduced section opposed to two kidney-shaped ports contained in the face of the 'valveplate,' which is stationary.

The 'cylinder barrel' rotates in contact with the 'valveplate' face in a state of hydraulic balance, initial contact being obtained by spring loading.

Each cylinder is fitted with a 'piston' connected by a ball-ended rod to the 'socket ring' which in turn is connected to the 'mainshaft' by a double universal joint.

The 'socket ring' rotates in a non-rotatable but pivoted member called the 'tilting box' 'Michell' type bearings being interposed to take the thrust and radial load. When the 'socket

ring' is vertical the pump is in the neutral or no-stroke position, but any deviation from the vertical imparts stroke to the 'pistons' and causes delivery through one of the 'valveplate' ports and return through the other.

The greater the tilt the more delivery given, owing to the increased travel of the pistons. By reversing the angle of tilt the flow will also be reversed, and what was previously the delivery port will become the return port.

Lever or wheel controlled pumps can be arranged to give delivery in both directions from zero to maximum, but in the case of pumps fitted with auto-pump control, as applied to operate rams, etc., tilt is usually applied in one direction only, and the flow from these pumps is therefore not reversible.

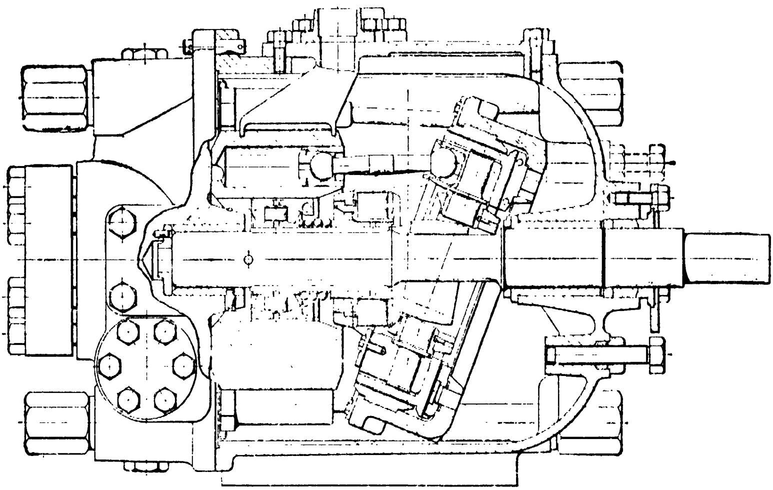

FIG. 1.

Two distinct types of pumps can be supplied, viz.: —

Lever or Wheel controlled Pumps.	To give variable delivery at fluid pressures up to the maximum pressure at which the relief valves are set, controlled by hand or mechanical means.
Automatic Pressure controlled Pumps.	To give automatically regulated delivery over a predetermined pressure range, or alternatively at a practically constant pressure. Delivery is controlled by the pressure of the fluid in circulation acting on rams connected to the tilting box in opposition to suitably rated springs.

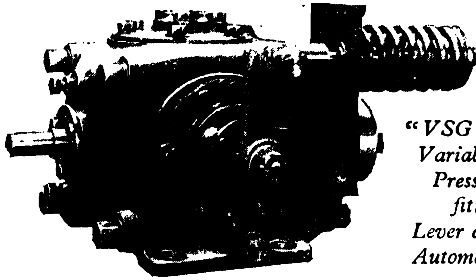
This pump also forms the 'A' end unit of the hydraulic transmission gear manufactured by this Company described below.

VARIABLE-SPEED GEAR.

THE 'VSG' MARK III. HYDRAULIC VARIABLE-SPEED GEAR.

(Vickers-Armstrongs Ltd. (Variable Speed Gear Dept.), Vickers House, Westminster, S.W. 1.)

This gear consists of two units, viz. an 'A' end or pump unit (fig. 2, p. 1116), and a 'B' end or hydraulic motor (fig. 3). These 'A' and 'B' ends can be opposed to one another directly with a common connecting plate termed a 'valveplate,' forming a type 'C' gear, or they can be separated to any reasonable distance and connected by piping, each unit having a separate valveplate, forming a type 'K' gear.



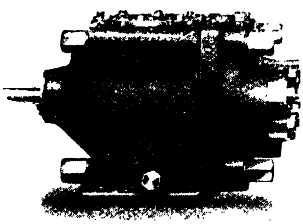
"VSG" Mark III Variable Delivery Pressure Pump fitted with Lever and External Automatic Control.

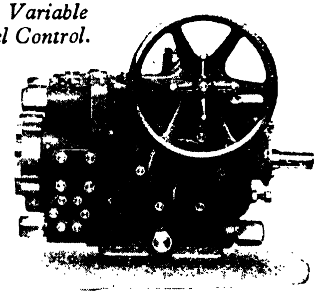
"VSG" VARIABLE DELIVERY PRESSURE PUMPS

(Regd. Trade Mk.)

SUITABLE FOR ALL SYSTEMS EMPLOYING OIL AS THE HYDRAULIC MEDIUM

Type "K" "VSG" Mark III Variable Speed Gear, fitted with Handwheel Control.





"VSG" HYDRAULIC VARIABLE SPEED TRANSMISSION GEARS

(Regd. Trade Mk.)

Infinite variation of speed without steps, forward and reverse. Positive control. High starting torque. Eminently suitable for controlling machinery for industrial purposes, viz.:—

Annealing Furnaces	Floorcloth Machinery	Photographic Paper and Film Treating Plant
Cable-Making Plant	Iron & Steel Works Machinery	Rubber Machinery
Colliery Plant	Linoleum Machinery	Textile Machines
Conveyors	Paper-Making Machinery	Wire-Making Machines
Coilers for Belts, etc.	Printing Machines	Woodworking Machines
Foundry Plant		

Also for Ship Machinery, including Steering Gears, Windlasses, Capstans, Boat Hoists, Winches, etc.

Extensively used for control of Ordnance, Director Firing Gear, Ammunition Hoists, and other special purposes where positive control is essential.

VICKERS-ARMSTRONGS LIMITED

(VARIABLE SPEED GEAR DEPARTMENT)

VICKERS HOUSE, WESTMINSTER, S.W.1.

Telephone: Abbey 7777. *Telegrams: "Varispeed, Sowest, London."*

F. 1114

The flexibility of arrangement possible with the ' VSG ' gears is a valuable feature, particularly so where considerations of space enter into account. Oil, which is practically incompressible, is the medium of transmission of power, and as this is supplied under pressure to the most important working surfaces and the whole of the machine casing is filled with oil, lubrication is perfect and wear negligible.

Construction.

The ' B ' end or hydraulic motor is generally similar in construction to the ' A ' end or pump unit, which is fully described above, a number of its components being identical with those of the ' A ' end. For the majority of purposes no controls or relief valves are necessary in the ' B ' end, and the tilting box is usually fixed, giving the ' B ' end a fixed capacity.

Where cooling is desirable, a water cooling coil is fitted in the ' B ' end around the cylinder barrel.

Whilst in some cases ' Michell ' type bearings are fitted to take the axial and radial thrust behind the socket ring in the ' B ' end, in certain equipments ' VSG ' ' B ' ends are fitted with roller bearings.

Operation of the Gear.

When a ' VSG ' gear is ready for running, the entire space within the cases and valveplate of the type ' C,' and valveplates and piping in the type ' K,' is filled with oil.

A definite portion of the oil is enclosed within the ' cylinders ' ahead of the pistons, valveplate port passages, and piping of type ' K.' This is the working oil used in transmitting energy, the case oil not being subject to pressure.

Assuming the tilting box with its socket ring is set at the neutral position (*i.e.* perpendicular to the mainshaft), the ' A ' end mainshaft, if rotated, will carry with it the socket ring and the cylinder barrel, together with the pistons and connecting rods. The pistons will not reciprocate or move to and fro in the cylinders, and as there will be no delivery from the pump, the ' B ' end will remain stationary.

If the control be moved a little, so as to move the top of the tilting box away from the ' valveplate,' and the ' A ' end mainshaft is rotated in a clockwise direction (looking on its shaft end) all the pistons as they move down on the right-hand side will be driven in towards the valveplate, expelling the oil contained in the cylinders through the cylinder ports and the large port in the same side of the valveplate. The ' B ' end, as is explained later, will then commence to rotate at a speed corresponding to the amount of delivery given by the ' A ' end.

The pistons on the left-hand side of the ' A ' end will, as they ascend, be drawn away from the valveplate, and their cylinders will fill with oil from the valveplate port facing them.

It should be noted that when a piston reaches the top or highest position in its revolution, and also the lowest position, it for an instant makes no end movement. This corresponds with the cylinder port crossing the top or bottom lands or spaces between the two valveplate ports.

The quantity of oil forced through the valveplate port depends upon the length of stroke imparted to the pistons and consequently upon the angle at which the tilting box stands.

The ' B ' end is an inversion of the 'A' end, and the ' B ' end socket ring is carried normally at a fixed angle of about 20°, the top of the angle box lying back from the valveplate, and when the ' B ' end mainshaft is rotated the ' B ' end pistons will make their full stroke as they pass between the bottom and top pistons.

The oil expelled by the 'A' end pistons through the pressure port of the valveplate enters the ' B ' end cylinders facing that port and exerts pressure on the pistons in those cylinders.

Due to the socket ring being housed in the angle box, the pistons cannot move except by rotating the socket ring in its bearings on the inclined plane, thereby converting the reciprocating motion of the pistons into rotary motion of the socket ring and the shaft to which it is connected.

The socket ring therefore revolves and carries with it the mainshaft to which it is connected by the universal joint. The ' B ' mainshaft in turn rotates its cylinder barrel, and the whole of the ' B ' end rotating group revolves in the opposite direction to the rotation of the 'A' end mainshaft.

The speed of rotation of the ' B ' end mainshaft depends upon the quantity of oil delivered by the 'A' end. For example, if each cylinder has a capacity of, say, 3 cu. ins., one complete revolution of the ' B ' end group of 11 cylinders would transfer 33 cu. ins. of oil from the right-hand side to the left-hand side. If the top of the 'A' end tilting box be tilted away from the valveplate sufficiently to cause the socket ring to impart a small stroke to the 'A' end pistons corresponding to an output from each cylinder of, say, 0·01 cu. in., all the 11 pistons of the 'A' end will together transfer 0·11 cu. in. of oil from the left-hand to the right-hand side at each revolution of the mainshaft.

On the basis of the capacity of the ' B ' end cylinders per revolution being 33 cu. ins., 300 revs. of the 'A' end mainshaft at this degree of tilt will be necessary to rotate the ' B ' end mainshaft once. If, however, the 'A' end socket ring be tilted still farther, the output of the 'A' end will be greater and the ' B ' end mainshaft will rotate proportionately faster, untilat full stroke both ends are at the same speed.

So far reference has been made to tilting the 'A' end socket ring in one direction only—namely, by moving the top of the tilting box away from the valve plate. If, however, it be moved in the

THE 'VSG' MARK III. HYDRAULIC VARIABLE-SPEED GEAR.

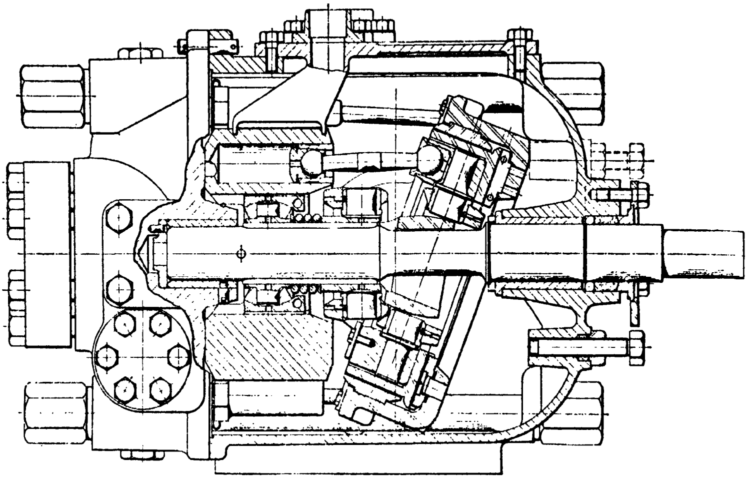


FIG. 2.—Vertical section through 'VSG' Mark III. 'A' end, fitted with lever control.

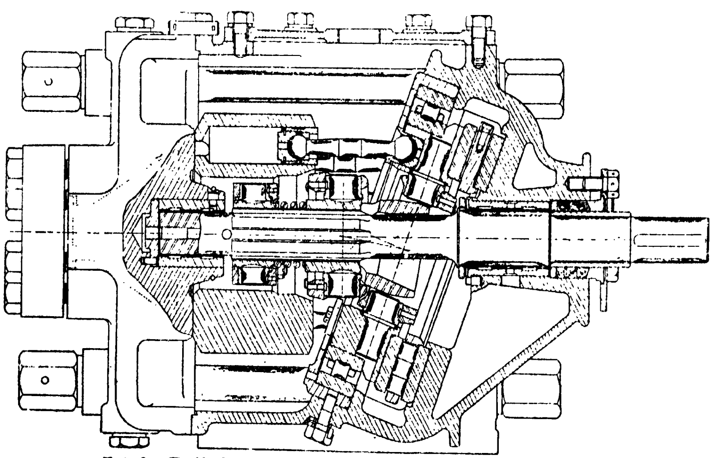

FIG. 3.—Vertical section through 'VSG' Mark III. 'B' end, fitted with roller type bearings.

opposite direction, the oil will be discharged through the left-hand port instead of through the right-hand port as previously; this will cause the 'B' end group to rotate in the opposite direction to that in which it has previously revolved, and it will now correspond in direction of rotation with the 'A' end mainshaft—viz. clockwise. The gear is therefore fully reversible.

When the 'A' and 'B' ends are of equal capacity, the maximum speed of the 'B' end mainshaft will be equal to that of the 'A' end, forward or reverse as required.

For some purposes 'A' and 'B' ends of different capacity are combined, usually a large 'B' end being employed, thereby giving a fixed reduction ratio as well as variable and reverse speeds.

Where a reduction or step-up gear is necessary on either the input or output shaft of the gear this can, in many cases, be arranged within the gear casing.

Controls.

Many forms of control have been developed to meet various requirements, these being designed basically to vary the stroke of the pistons of either 'A' end or 'B' end units, or both, as desired, giving perfectly smooth and stepless speed variation, although valve controls are also employed in some cases.

In its simple form the control may consist of a lever mounted directly on an extension of one of the tilting box trunnions or a rotary shaft or handwheel operating through gears directly on the top of the tilting box, for manual or mechanical operation.

It is also possible to synchronise and/or link the controls of a series of machines so that predetermined relative speeds can be maintained. Remote control is a frequent requirement and can be arranged hydraulically, electrically or mechanically to suit the conditions obtaining.

Various types of automatic control operated by pressure generated in the hydraulic system have also been devised. By this means automatic reduction of 'A' end delivery as oil pressure rises can be arranged, or, under certain conditions a constant oil pressure ensured irrespective of delivery.

The characteristics of such controls ensure that the pre-determined torque and horse-power are not exceeded whilst retaining the ability of the gear to work over a large speed and torque range. In the event of overload the control stalls the gear without risk of damage or stopping of the prime mover and obviates the necessity of using skilled operators to safeguard the equipment. It is a very valuable feature where dealing with loads which may vary considerably or where obstructions are likely to be encountered.

Automatic controls when fitted to 'VSG' pumps operating self-contained hydraulic systems such as on presses, render the fitting of accumulators unnecessary.

It should also be mentioned that pressure control of 'B' end tilt can also be provided so that in cases where constant horse-power is required such as in a coiling drive, where the linear speed and tension of the material to be dealt with must be maintained at pre-determined rates, this can be achieved automatically by the pressure in the system.

Advantages.

The special properties of the 'VSG' Hydraulic Variable Speed Gear can be summarised as follows:—

(1) Speed change without declutching from prime mover.
(2) Ability to 'inch' and rotate at very low speeds.
(3) High torque at low speed.
(4) Perfectly smooth acceleration and retardation at any constant or variable rate.
(5) Quick reversibility without shock.
(6) Complete positive and simple control in either direction.
(7) Steady speed under fluctuating loads.
(8) Enables constant speed non-reversing prime mover to be used.
(9) Protects complete installation from damage due to overloads.
(10) Reduces labour and operating costs.
(11) Repairs and maintenance negligible.

An important feature inherent in the 'VSG' gear is the braking effect which can be obtained when it is used with a regenerative prime mover, enabling the retardation of masses having large momentum and unbalanced loads to be carried out under absolute control, *e.g.* in the case of a hoist, loads may be lowered at any desired speed, decelerated and held in all positions without the use of mechanical brakes. In fact, the same degree of control is available when lowering as when hoisting.

With electrically driven machinery a distinct advantage is obtained by the use of the 'VSG' gear, inasmuch as the simplest and cheapest type of motor can be installed, *i.e.* squirrel cage induction or shunt wound DC., also controllers and resistances with their attendant heavy current losses are dispensed with, a light load starter only being necessary. Current peaks when starting heavy loads are eliminated.

THE EXACTOR 'SELF-SEALING' PIPE COUPLING.

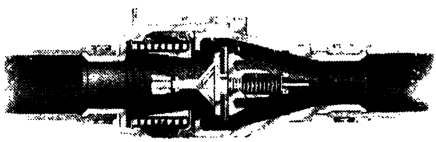
(World Patents.)

(*Exactor Control Company, Ltd.*, 14 *Berkeley Street*, *London*, *W.* 1.

The Exactor Self-sealing Pipe Coupling is a coupling with a double function. First, to bring two pipe lines into connection. Second, to seal off each pipe line when disconnection has to be made.

It is therefore by turn an orthodox coupling and an automatic sealing device. This double function is effected by means of a two-part construction. When the two parts are joined, the device resembles and functions like a normal pipe coupling. When separated, each half acts as a seal on the pipe line to which it is attached.

The automatic sealing function ensures that there is no escape of the liquid or gas—not even a 'dribble'—when disconnection is made, and eliminates the need for operating any supply cock or for draining down.



CONNECTED.
Full-bore flow through coupling.

DISCONNECTED.
Both halves completely sealed off.

Re-connection is an equally simple and swift operation, free from spillage or air trapping. The range of standard Exactor Self-sealing Couplings covers medium-pressure systems up to 300 lbs. per sq. in. or high-pressure systems up to more than 2,500 lbs. per sq. in., in sizes from ¼-in. bore to 4-in. bore and upwards. They are serviceable for a variety of fluids, from hot oil to refrigerants, under any conditions of vibration or severe treatment.

Description of Operation.

Each half of the device contains a resilient-faced sliding valve, spring-loaded on to its seat. As the two halves connect by screwing home the outer ring, the two springs are compressed and the valves slide back. Thus a full-bore flow path is created between the two pipe lines.

The process works in reverse as the outer ring is unscrewed to effect disconnection, viz., the two springs gradually extend, progressively close the valves and so close the flow path as the resilient valve-faces come to rest on their seatings.

At this stage, the two halves are still engaged but the pipe lines are now effectively sealed. A few more turns of the ring then disengages the two halves of the coupling and the pipe lines are entirely disconnected.

The patented features of the device provide against leakage of the smallest degree whilst two pipe lines are connected and whilst they are in process of connection or disconnection. All tests for leakage or air trapping give a 'Nil' result.

THE EXACTOR PIPE-LINE CHANGE-OVER SWITCH.

The Exactor Pipe-line Change-over Switch is a device based upon the use of the Exactor 'Self-sealing' pipe coupling described in the foregoing paragraphs.

It provides a method of switching hydraulic pipe lines of all kinds from one alternative supply circuit to another with a precision and speed analogous to the switching of electric conductors.

It has been designed to overcome all the shortcomings of a change-over effected by manual operation of individual separate cocks or valves, and makes incorrect combinations or 'crossed' circuits impossible. Each pipe in the system must be either positively engaged or positively sealed off.

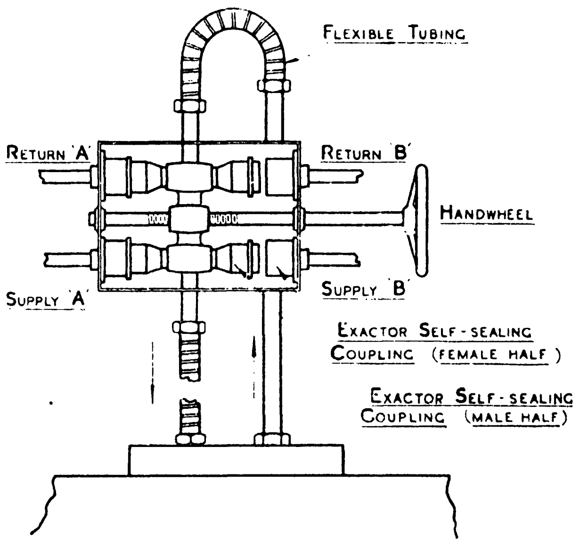


Diagram to illustrate working principle of Exactor Pipe-line Switch.

Apart from its fool-proof character, the Exactor Switch Unit has been proved in service to offer great savings in time required to effect a change-over.

Typical Uses.—To switch the circulation through an apparatus from hot water (or steam) back to cold water and *vice versa.* Many rubber calendering rolls and press platens have been equipped with Exactor Switch Units for this purpose.

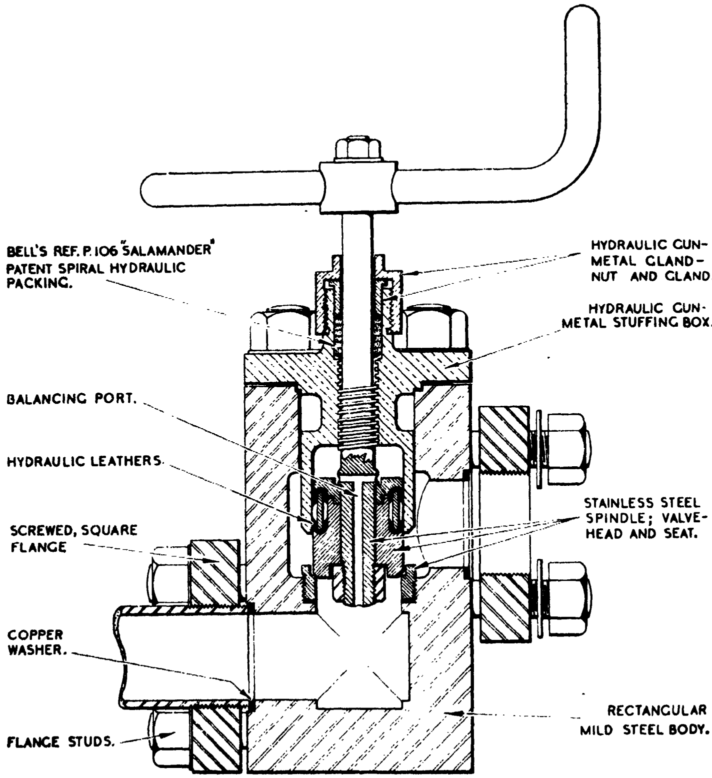
Description of Operation.—As the handwheel is rotated in either direction, the threaded portion of its spindle causes the central carriage to move to the left or to the right accordingly. Thus the carriage will engage alternatively the circuits marked 'A' or 'B' on the diagram, and so determine the service circulated through the jacket or other chamber represented at the bottom of the diagram.

The Exactor Self-sealing Couplings slide together or apart without any spilling or air inclusion and their progressive action permits throttling control by the handwheel.

High Pressure Balanced Hydraulic Stop Valve.

(Bell's Asbestos and Engineering Limited, Slough, Bucks.)

Modern hydraulic equipment frequently operates at pressures of several tons per sq. inch. The special balanced action of the 'Bestobell' high pressure hydraulic stop valve ensures easy opening and closing even at maximum line pressure, and avoids the use of a by-pass fitting.



The balanced action is produced by means of a small port drilled up the centre of the lower part of the valve spindle, causing pressure to act on both the upper and lower surfaces of the valve head. By this means finger-light manipulation can be obtained.

The valve body is constructed from a solid mild steel billet, and the spindle, valve and seat are of stainless steel.

The standard valve is designed for pressures up to 3,000 lbs. p.s.i. and a heavier type is available for pressures of 6,000 lbs. p.s.i. and over.

SECTION XIX

PART III

Pumps and Pumping.

THE CLARKE CHAPMAN DIRECT-ACTING FEED PUMPS.

(Woodeson's Patent.)

(*Clarke, Chapman & Co., Ltd., Gateshead-on-Tyne.*)

The single-cylinder direct-acting type of pump, on account of the small number of working parts and consequent small liability to break down, is very largely employed. Figs. 1 and 2, p. 1122, show Woodeson's 'Simple' Patent Direct-acting Pump. This pump, which is extensively used, works with all steam pressures up to 400 lbs. per sq. in.

The steam chest is manufactured of the best hard close-grained cast-iron, of a suitable thickness to withstand any tendency to distort through the temperature of high-pressure steam.

The working parts of the steam chest consist of one auxiliary valve and one main valve, both of piston valve type.

The auxiliary valve is operated by the valve gear, actuated by the piston-rod crosshead. The main valve is partly moved mechanically and partly operated by steam, controlled by the auxiliary valve.

The action of the valves is as follows :—

When the main piston is nearing the end of its stroke, and the auxiliary valve commences to be moved by the valve gear, the first part of the movement closes the port through which the exhaust from one end of the main valve has been passing. The next part of the movement of the auxiliary valve opens steam to this end of the valve, and as the steam to the opposite end has not been closed, the main valve is in equilibrium. By the time that this takes place the auxiliary valve has moved so as to be in contact with the main valve, and further movement of the valve gear causes the auxiliary valve to move the main valve mechanically and so close the ports to the main cylinder. When these ports are nearly closed the auxiliary valve has closed the steam port at the end of the main valve, towards which the valves are moving, and opened an exhaust port, with the result that the main valve is moved by steam to the end of its travel and the steam cylinder ports are opened for the return stroke.

Should the main valve by any chance be delayed in being moved by steam, it would be worked mechanically during the clearance in the steam cylinder to a sufficient extent to open the steam port at the end of the cylinder towards which the piston was moving, and so forming a steam cushion to prevent the possibility of the piston striking the cover.

Advantages of the gear are :—

The main and auxiliary valves can all be mechanically actuated from the outside; this is an advantage if the pump is standing for any length of time, as it keeps the faces from getting rusted up.

During the process of the mechanical movement, the piston to which this movement is imparted is in perfect equilibrium.

There is entire absence of valve setting.

These pumps are also made on the TANDEM COMPOUND principle. Great economy has been obtained with the pumps, and they are specially applicable for electric power stations and other high-class installations where economy of steam is an important consideration.

Fig. 3, p. 1122, shows a pair of these pumps fitted with automatic controlling gear, as used for MAIN INDEPENDENT FEED-PUMPS FOR MARINE PURPOSES; with this automatic controlling gear there must be no dead points, and the pump must be able to start from any position, this being a special recommendation for a feed-pump for marine purposes, where, in order to derive all the benefits to be gained by using independent main feed-pumps, the speed of the feed-pumps must be automatically regulated according to the quantity of water to be dealt with, which varies with the speed of the main engines. The 'Woodeson' pump contains all the necessary features for this work.

No flat surfaces exist in any part of the water end exposed to pressure. Both suction and delivery valves are arranged in groups, and are easily accessible for overhauling. The plunger junks are of gunmetal, and are fitted with composition plunger rings, specially manufactured to deal with high pressure and high temperature.

Test taken with Clarke, Chapman Simple Type of Slow Speed Feed-Pump (Woodeson's Patent) :—Diameter of steam cylinder, 10½ ins.; Diameter of water cylinder, 8 ins.; Length of stroke, 18 ins.; Water delivered per lb. of steam used, 81 lbs.; Steam used per water h.p. hour, 59·5 lbs.; Steam pressure per sq. in., 180 lbs.; Pressure in discharge pipes per sq. in., 195 lbs.; Volumetric Efficiency of pump, 97 per cent.

Test taken with Clarke, Chapman Tandem Compound Type of Slow Speed Feed-Pump (Woodeson's Patent) :—Diameter of h.p. cylinder, 8½ ins.; Diameter of l.p. cylinder, 13 ins.; Diameter of water cylinder, 8½ ins.; Length of stroke, 18 ins.; Water delivered per lb. of steam used, 110·5 lbs.; Steam used per water h.p. per hour, 36·5 lbs.; Steam pressure per sq. in., 195 lbs.; Pressure per square in. in discharge pipes, 215 lbs.; Volumetric Efficiency of pump, 97 per cent.

CLARKE CHAPMAN STEAM PUMPS.

FIG. 1.

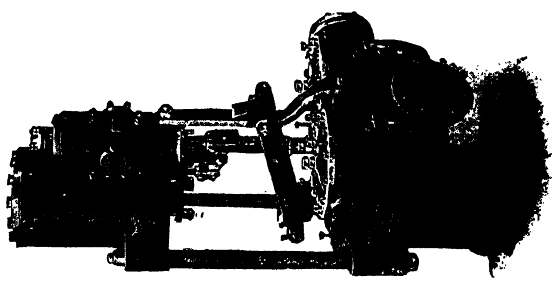


FIG. 2.

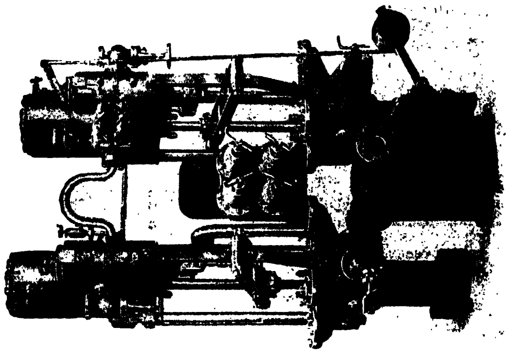

FIG. 3.

MADAN'S AIRHYDROPUMP.

(*Charles S. Madan & Co., Ltd., Vortex Works, Broadheath, Altrincham.*)

This machine is an air operated hydraulic ram pump providing a small supply of water, oil or kerosene at any desired pressure within limits, at the expense of a small quantity of compressed air taken from the usual air line found in most engineering shops.

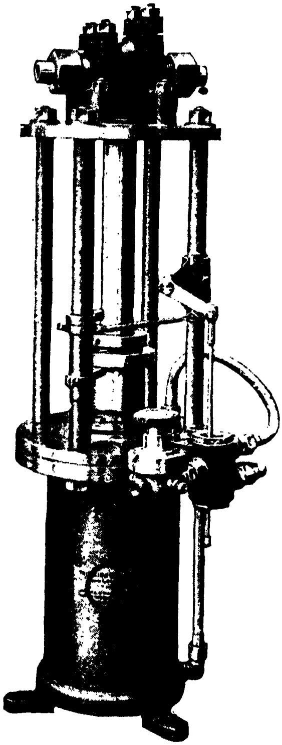

FIG. 1.—Single-Acting Pump.

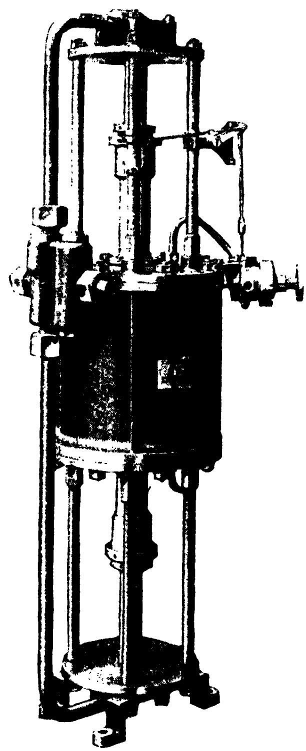

FIG. 2.—Double-Acting Pump.

The following description will serve to explain how the pump works:—

A double acting air pressure cylinder and piston are provided, and the movement of the piston is imparted to a water cylinder containing a fixed ram. The air piston being of larger diameter than the ram, an increased pressure is produced in the water cylinder.

In operation, so long as the total load in the water cylinder is less than that in the air cylinder, the pump will continue to function and will automatically reverse at the end of each stroke. When the pressure builds up so that the loads are equal the pump comes to rest, but restarts as soon as the balance is disturbed.

The hydraulic pressure is regulated by a simple control valve on the air supply, which may be left set at any desired pressure.

Models are made giving maximum pressures of 40 to 15,000 lb. per sq. in. hydraulic, with air at 100 lb. maximum pressure.

The pump weighs from 110 lb. to 260 lb. according to type.

THE PULSOMETER STEAM PUMP.

(*The Pulsometer Engineering Co., Ltd., Reading.*)

In this pump, figs. 1 and 2 (general view), the neck J contains a gun-metal ball I, above which is a steam pipe K. EE are suction valves placed at the base of two chambers AA. Immediately above the suction valves the two chambers communicate with a 'discharge box'

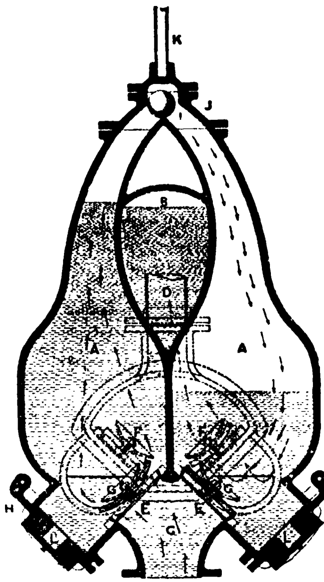

FIG. 1.

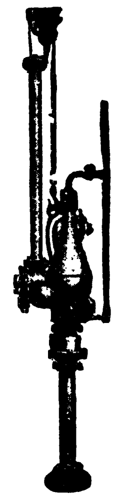

FIG. 2.

The Pulsometer Steam Pump.

through two discharge valves FF. The valves in the standard pattern of pump are of the grid type, consisting of a grid, rubber, and guard. In addition to the above valves there are three small gun-metal valves (not shown in the figure) for the admission of air, one of each being screwed into the upper part of the two water chambers and the air vessel.

Action.

Assuming one of the chambers to be open to steam and full of water, the steam entering by the steam pipe and past the ball passes into the chamber and presses upon the small surface of water exposed, depresses it without agitation (and therefore with little condensation), and drives it (as seen in the figure) through the discharge valves FF into the rising main, D. The moment the water in the chamber falls to the level of the opening in the branch leading to the discharge box, the steam blows through with a certain amount of violence, and as it is brought into intimate contact with the water in the discharge box an instantaneous condensation takes place, and the vacuum thus formed in the emptied chamber immediately pulls the control ball over on to the corresponding seat and cuts off further admission of steam, allowing the vacuum to be completed. Water immediately enters through the suction pipe, and lifting the inlet valve rapidly fills the chamber again. A similar operation has been taking place in the fellow chamber, the period occupied by filling one chamber corresponding to that of emptying the other, and these operations continue alternately in the two chambers so long as the pump is supplied with steam and water. The function of the air valves is to introduce a small quantity of air at each stroke or 'pulsation' for the purpose of cushioning the ball when it changes its position, and for separating the steam from the water by a non-conducting film so as to prevent loss by condensation during the expulsive portion of the cycle.

The 'Pulsometer' Steam Pump is largely used by contractors for pumping from excavations for the following reasons: it works equally well when fixed or suspended from a chain or rope; its small size proportionate to the quantity of water thrown makes its use possible where other pumps cannot be used; and it can pump water heavily charged with mud and sand.

The 'Pulsometer' Steam Pump will work day and night without attendance so long as steam and water are supplied and conditions remain constant.

TURBINE PUMPS.

(The Pulsometer Engineering Co., Ltd., Reading.)

Fig. 3 shows a typical example of a high lift turbine pump suitable for water supply, mine drainage, boiler feeding and similar duties.

The pump consists of a number of cells bolted together, each with its own impeller, the water leaving one impeller to pass through a diffuser to the next. It is, therefore, simple to arrange for a series of impellers which together are capable of giving total heads up to 3,500 ft. or more.

To keep the overall length of the pump within manageable dimensions, each impeller is of the single entry type. The areas of the two shrouds therefore differ by the area of the impeller eye, and an axial thrust is set up equivalent to the total pressure the pump is developing multiplied by this area. A hydraulic balancing device in the pump takes up the thrust more simply and reliably than any mechanical thrust bearing. Fixed to and revolving with the spindle is a balancing disc, its periphery moving just clear of a seat fixed to the delivery cover. Having no collars on the spindle, the whole rotating element is free to move axially when the pump is at rest. On starting up, however, the out-of-balance thrust moves the shaft axially towards the suction, reducing the clearance between the disc and the seat, thus building up a difference in pressure between the two sides of the balancing disc. This building up process continues until the difference in pressure balances the axial thrust towards the suction, the area of the disc being calculated to hold the rotating element in position against the axial thrust with a fine clearance between disc and seat which keeps the water passing the balance disc down to a negligible quantity.

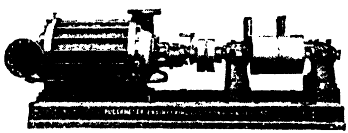

FIG. 3.

The balance chamber into which this water discharges is connected back to the pump suction branch. Therefore, no matter what head the pump is working against, the delivery gland is subject to suction pressure only.

Absence of all metallic contact in the pump means that there will be no wear except when gritty water is pumped. A gauge provided to indicate any wear taking place on the balancing device, makes possible the adjustment and restoration of the pump to its original efficiency.

CENTRIFUGAL PUMPS.

(The Pulsometer Engineering Co., Ltd., Reading.)

The pump shown in fig. 4 is a good example of the present-day trend in centrifugal pump design. The casing is arranged in two halves and is split along the horizontal centre line, the suction and delivery branches being cast in the bottom half of the casing, which is bolted to the pump bedplate. By this means it is possible by the simple expedient of removing the top half of the casing or cover to inspect the whole of the interior of the pump and, if necessary, even remove the rotating element, without in any way interfering with the alignment of the pump or breaking the pipe joints. The impeller, which is of the double entry type, is inherently self-balancing and so no axial thrust is set up while the pump is in operation, a light locating thrust bearing being provided to centre the shaft when the pump is being started up or shut down.

The shaft being supported at each end in a sleeve or ball bearing makes the pump particularly suitable for water which contains a little grit or other abrasive material. Renewable

rings are fitted in the casing where the impeller runs with a fine clearance, so that the clearance can be simply and cheaply restored and the pump brought back to its original efficiency. The glands normally are sealed by water bye-passed from the discharge side of the pump, but again, when abrasive materials are to be handled, it is a simple matter to convert the pump so that the glands are sealed by grease or by an external supply of clean water.

This form of split casing construction is also extended to two-stage pumps and multi-stage pumps where the head to be developed by the pump is higher than can be efficiently obtained with a single impeller, and the accessibility to the internal parts of the pump is of considerable advantage. In the case of the two-stage pump this is arranged with the impeller eyes facing outward, the suction branch communicating with the eye of the first-stage impeller, the delivery from which is carried through volute passages crossing over the second stage to the eye of the second impeller and then to the delivery branch. By this means it is possible to balance the hydraulic thrust on the impeller, and the shaft is definitely located by means of an external ball thrust bearing, generally as described above.

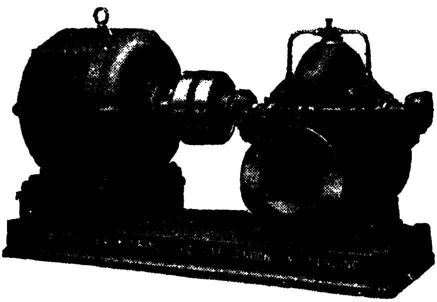

FIG. 4.

When this construction is extended to the multi-stage pump, complicated construction and high pressure delivery end stuffing box are avoided by mounting the impellers all the same way, passing the water direct from the first to the second impeller in series, and providing a balance disc to balance the hydraulic thrust as in the case of the turbine pumps previously described.

Single Entry Centrifugal Pumps.

For industrial and general service applications a very comprehensive range of end suction single-stage pumps can be used. These are arranged with vertical flanged joints and single entry overhung impeller, which is hydraulically balanced either by means of a ring at the back of the impeller inside which is a space connecting with the suction side of the pump, or by means of balancing vanes. Either of these methods have the object of balancing the hydraulic thrust and relieving the pressure on the stuffing box of the pump which is located as close as possible to the back of the impeller.

In some cases where the pump is handling perfectly clean water, and other liquids having comparatively good lubricating properties, it is possible to incorporate an internal bearing in the stuffing box immediately behind the impeller, and one external bearing arranged to share the journal load and locate the rotor in its correct position.

A more reliable arrangement, particularly for those pumps handling dirty water and liquids having no lubricating properties, can be embodied in the Pulsometer pumps of this type. In this design the rotating element is carried on two well spaced external bearings, one being placed as close as possible to the overhanging impeller, and the other one arranged to share the rotating weight and prevent any mechanical contact in any part of the pump, except through the gland packing. The inner bearing locates the pump rotor axially, and the outer bearing is normally a roller bearing which would be suitable for carrying a comparatively heavy belt pull for overhanging pulley drive. Adaptations of this type of pump have been provided by the Pulsometer Engineering Co. for handling a very diverse range of liquids, and the working parts of the pump can be provided in materials which include special irons and steels, bronzes, stainless steel, ebonite, rubber and stoneware.

Direct-Acting Feed Pump.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S. 4.)

The Weir Patent Direct-Acting Feed Pump, shown in fig. 1, p. 1128, is the original of a type of pump which is largely used. Introduced at first for marine boiler feeding, its adoption by the mercantile marine, the British Navy, and numerous foreign navies, caused it afterwards to be placed on the market in a form suitable for land installations, power plants, etc.

The valve gear is positive—*i.e.* the steam valve can never be in such a position that the pump will not start immediately when steam is turned on. The only possible way in which the main valve can rest is at full travel, either for an up or down stroke of the piston. The valve arrangement also ensures constant length of stroke and certainty of action.

The steam valve is a D slide-valve, with a small auxiliary slide valve working on the back, and hence has not the same liability to leak as a piston valve. These are the only two moving parts proper in the steam chest, so that there is little opportunity for wear, and no delicate adjustments to get out of order. The steam is used expansively, and the cut-off can be regulated from the outside while the pump is working.

The water valves are of the Weir group type, providing a large area with only a small lift, thus ensuring easy working and little wear and tear. The pumps are designed to work at a moderate speed and the piston is slowed down towards the end of the stroke, enabling the valves to settle quietly on their seats. The working and maintenance of the pumps is therefore much more satisfactory than in pumps running at a high speed. In the matter of steam consumption, numerous tests and comparisons show that the Weir pump is highly economical; this is due to the fact that it has fewer ports and passages than a duplex pump, and the simple expansion arrangement enables it to be built so that the clearance is small.

Where it is desired to regulate the boiler feed automatically, a special design of float tank and regulating gear is furnished.

The Weir Feed Pump is more extensively used than any other type for feeding water tube boilers; these contain a relatively small quantity of feed water and to maintain a constant water level in the boiler for continuous steady steaming the feed pump must be capable of providing a regular and uninterrupted supply of feed water at any pressure necessary. For this service the Weir Pump is unequalled on account of its slow steady movement and complete reliability under any pressure. The pump can work in conjunction with any of the recognised types of boiler feed regulators.

For steam wagons, rail coaches, cranes, and all small stationary or portable boilers, a horizontal pump known as the Weir Junior Feed Pump is built, for capacities up to 130 galls. per hr.

11. Piston body.
12. Piston rings.
13. Cylinder cover.
14. Discharge valve seat.
15. Discharge valve seat ring.
16. Suction valve seat.
17. Suction valve guard.
18. Discharge valve guard.
19. Water valves.
20. Bucket.
20A. Bucket rings.
21. Pump rod.
22. Pump cover.
23. Valve chest cover.
24. Steam stop valve.
25. Exhaust stop valve (when fitted).
26. Auxiliary valve spindle.
27. Cylinder neck-ring.
28. Cylinder gland.
29. Pump neck ring.
30. Pump gland.
31. Pump liner.
32. Liner fixing pin.
33. Pump gland studs.
34. Cylinder gland studs.
35. Suction and discharge columns.
36. Top pins.
37. Ball crosshead bushes.
38. Piston rod nut.
39. Pump rod nut.
40. Crosshead taper pin.
41. Pump drain plug.
42. Plunger lubricator.
43. Adapter for lubricator.
44. Ball valves and spring for lubricator (not shown).
45. Gland packings complete.
46. Pump and cylinder joints.
47. Cylinder drain valve.
48. Discharge valve spring.
49. Suction valve spring.

Turbo-Feed Pump.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S. 4.)

Weir Turbo-Feed Pumps are built in both single and multi-stage types and the range of sizes covers all boiler feeding requirements from 4,000 galls. per hr. upwards.

The driving unit consists of a steam turbine of the impulse type, having one pressure and several velocity stages. The turbine casing and bearing housings are divided horizontally, the lower portions being embodied in the general framework or base. This framework is extended at the

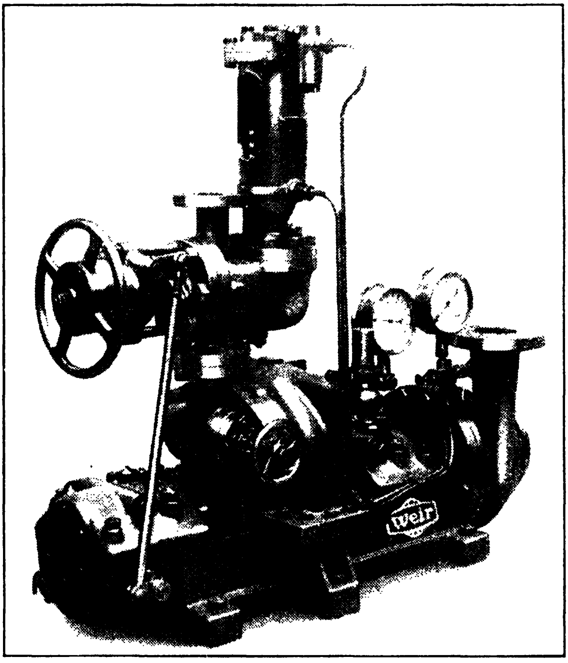

Fig. 2.—The Weir Single-Stage, Two-Bearing Turbo-Feed Pump.

pump end to form a flange to which the pump is bolted. In the single-stage, medium pressure type, the impeller is carried on the over-hung shaft, while in the high pressure type an outer pump bearing is added to prevent shaft deflection under load. The multi-stage pumps are all of the three-bearing type. The supports of the pump and turbine are arranged so as to ensure alignment under all operating conditions, centre-line suspension being employed in many cases where temperatures are very high.

The pump is self-regulating for all ordinary changes in water and steam conditions, a pressure operated governor, working a balanced double-beat throttle valve, being fitted. Auxiliary nozzles may be brought into use by a hand-operated valve when required. An emergency governor of the eccentric ring type is provided, which, in the event of the speed of rotation exceeding a predetermined limit, actuates a trip gear which releases a spring and instantaneously closes the stop valve; there is thus no possibility of the speed of the set reaching unsafe limits in the event of an accidental failure of the water supply.

The turbine glands are provided with carbon packing, and all parts are readily accessible for examination and overhaul. The pump is fitted with a hydraulic device which automatically balances the end thrust on the shaft.

The pumps are capable of discharging against the highest boiler pressures, and can be used in conjunction with other centrifugal or reciprocating pumps. An automatic cut-in device can be supplied for use when the pump is installed as a standby.

The Weir Turbo-Feed Pump is a high speed unit with a correspondingly low steam consumption. Further, as the exhaust steam is free from oil, it may be used for feed water heating by direct contact, thereby utilising all the heat in the steam. A special nozzle heater can be supplied for this purpose.

Multi-Stage Centrifugal Pumps.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S. 4.)

The Weir 'Electrofeeder,' a typical example of which is shown in fig. 3, is a multistage pump for boiler feeding, built for capacities of 4,000 galls. per hr. upwards, and for all pressures up to 2,300 lb. per sq. in. It is designed to be inherently stable in operation—that is to say, the pressure-volume characteristic curve falls continuously from zero to maximum output. The pump is therefore suitable for operation in parallel, either with similar pumps or other types possessing stable characteristics, without surging.

The type shown is of ring-section construction, the end covers and sections being bolted together by heavy tie bolts, the whole being mounted on a rigid baseplate which also carries the driving motor. The impellers are of the single inlet type, fitted to the shaft with keys at 180° to ensure ease of removal and freedom from shaft distortion. To take the end thrust

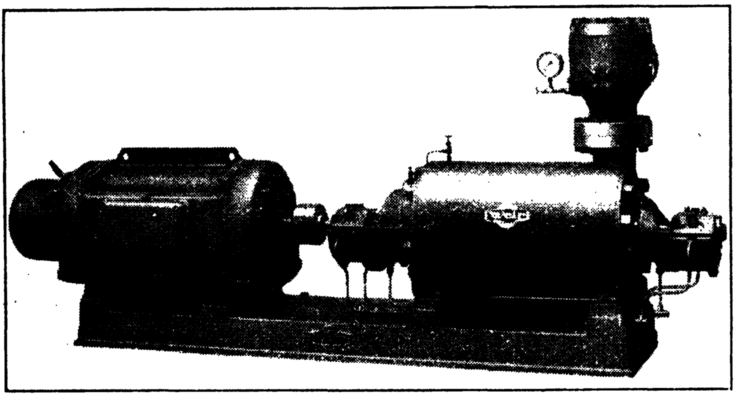

FIG. 3.—The Weir 'Electrofeeder,' Ring Section Type.

a hydraulic balance device is incorporated. The pump shaft itself is very carefully balanced dynamically, and a flexible coupling is employed between the pump and the driving motor.

Pumps of this type have been supplied for a large number of important power stations, capacities ranging up to 1,000,000 lb. per hr. Barrel casing type pumps are also built and are specially suitable for high temperature installations. Special designs, including main and booster units, electric-driven sets with turbine standbys, and complete turbo-electric sets in which the electrically driven unit operates at constant speed and at approximately boiler pressure while a steam turbine driven booster pump supplies the additional variable pressure increment according to the load, are also supplied.

Centrifugal pumps of somewhat similar design, but employing a barrel casing, and special methods of support to minimise the effects of expansion due to high temperatures, extra heavy construction throughout, special gland design, etc., are also supplied for handling hot oil in refineries, etc.

For both boiler feeding and refinery duty, the working conditions are extremely arduous, and great care has to be taken in the selection of the materials to withstand the effects of high temperatures, erosion and corrosion, etc.

SECTION XX

PART I

Ball and Roller Bearings.

TIMKEN TAPERED ROLLER BEARINGS.

(British Timken Ltd., Birmingham and Northampton.)

DESIGN.

The basis of the design of the Timken Tapered Roller Bearing (see Fig. 1) is founded on the only fundamentally correct principle for true rolling, which requires that the apices of the cones embracing the three rolling surfaces shall meet in a common point on the axis of revolution of the bearing.

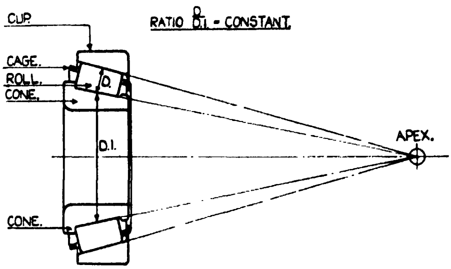

FIG. 1.—Component parts. Tapered Roller Bearings.

This principle is expressed by the equation :—

$$\text{Ratio } \frac{\text{D1}}{\text{D}} \text{ at any point along the roller} = \text{Constant.}$$

giving a constant angular velocity of the roller at any point along its length, otherwise slipping and skewing of the rollers will take place.

The main characteristics of the bearing are :—

(1) High carrying capacity for thrust and radial loads due to the long line contact between rollers and races.

(2) Ability to withstand simultaneously any combination of thrust or radial loads. A two-bearing mounting will effectively resist loads coming from all directions simultaneously.

> *N.B.*—Thrust and radial loads are both transmitted radially through the bearing at right angles to the respective lines of contact, utilising the full length of the rollers.

(3) Adjustability without interference to the geometry of the bearing, maintaining original alignment.

(4) Versatility in bearing design providing any ratio of thrust to radial capacity, determined by choice of apex position (see Fig. 2).

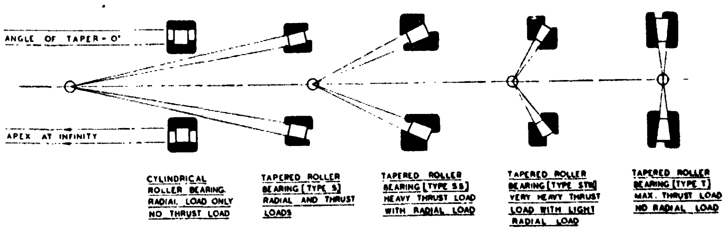

FIG. 2.—Geometric design of Tapered Roller Bearing.

(i) Apex at infinity—Cylindrical roller bearing having radial capacity only.

(ii) Apex as shown—Normal Timken Bearing (Type 'S') for heavy radial and normal thrust loads.

(iii) Apex closer to bearing—Timken Steep-Angle Bearing (Type 'SS') for heavy thrust loads and normal radial loads.

(iv) Apex in central plane of bearing—Timken Thrust Bearing (Type 'T') for thrust loads only.

(v) Low co-efficient of friction, 0.002 to 0.003 for normal loads and speeds, according to whether oil or grease lubrication is used. Value is practically constant for all speeds.

(vii) The bearing is its own oil pump. The tapered rotating elements set up a centrifugal action, which draws oil through the bearing from the small to the large ends of the rollers. Used in practice on machine tool spindles, railway axleboxes, etc., to provide an automatic oil circulation system (see Fig. 9, p. 1136).

(viii) Can be run at high speeds given an adequate lubrication system.

Types of Timken Bearings.

A general indication for the uses of each type is as follows :—

Type 'S.'	—Widely used in general engineering, automobiles and some railway axleboxes.
Type 'SS'	—General thrust load applications.
Type 'SF'	—Machine tool spindles. Facilitates accurate machining of headstock bearing housing bores, by eliminating internal shoulders.
Type 'DI'	—Widely used in railway axleboxes.
Types 'DO' and 'NA'	—For heavy radial loads, *e.g.* large reduction units.
Types 'DOS' and 'NAS'	—Alternating thrust loads, *e.g.* wormshafts.
Type 'QO'	—Used on work roll and back-up roll necks in all classes of rolling mills.
Type 'T'	—Pure thrust applications, *e.g.* crane hooks, swing bridges, automobile steering pivots.
Type V.P. Airscrew	—Special two-row bearings designed as sole support of blades of Variable Pitch Airscrews. Very high thrust capacity, with sufficient radial capacity for positive centring of blade, and races and rollers arranged to offer maximum resistance to tilting loads set up by air pressure, blade inertia and gyroscopic effects.

The multi-row bearings are combinations formed from single-row bearings of their respective types, and all conform to the basic principle of design—Fig. 1.

Bearing Mountings.

Timken bearings are practically always mounted in pairs, two fundamental methods being used (see Fig. 3).

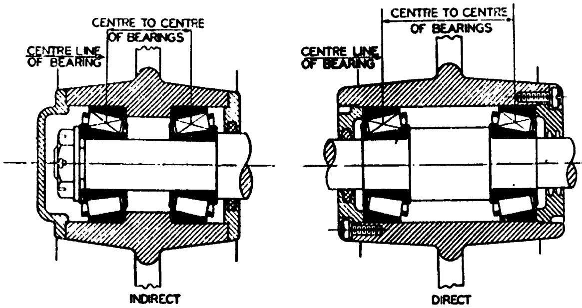

Fig. 3.—Method of mounting Timken Bearings.

Indirect Mounting.—Small ends of rollers point inwards. Used for limited bearing spacings and where the maximum resisting moment against tilting loads is required, *e.g.* machine tool, spindles, wheels.

Direct Mounting.—Small ends of rollers point outwards. Used for wide bearing spacing, and where adjustment of bearings by the cups is desired.

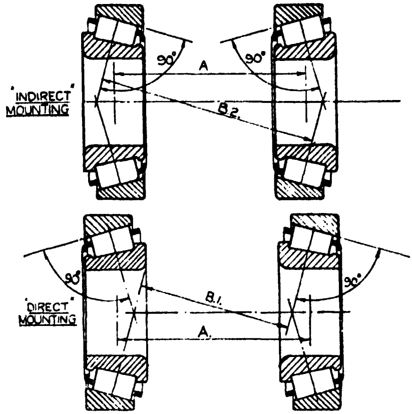

FIG. 4.—Effective Bearing Spacing.

The greater stability of the Indirect mounting is shown by a comparison of the actual effective spacings, B1 and B2 for equal axial spacings A, Fig. 4.

FITTING PRACTICE.

A good general principle is to make the revolving member a press fit to prevent slip, the stationary member being a close sliding fit for bearing adjustment. Operating, manufacturing or assembly requirements may conflict with this principle, when a compromise solution should be sought to take care of the most important requirements.

SHAFT AND HOUSING DESIGN.

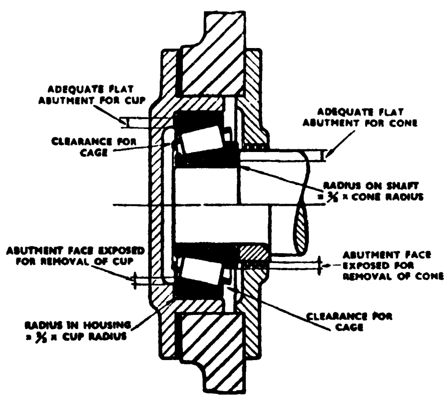

FIG. 5.—Details of Shaft and Housing Design.

Essential points in the detail design are shown in Fig. 5, which is self-explanatory.

ADJUSTMENT.

It is usual to allow a few thousandths of an inch endplay in a pair of bearings, according to the type of application and the operating requirements. A light preload of a few lb. ins. is sometimes given in special applications. Adjustment is made by moving one member of a pair of bearings. Two common methods are shown—by nut in Fig. 3 and by shims under the cover flange in Fig. 5. Fig. 5 shows the cup press-fitted into the cover spigot, and allows easy adjustment.

DOUBLE BEARING MOUNTINGS.

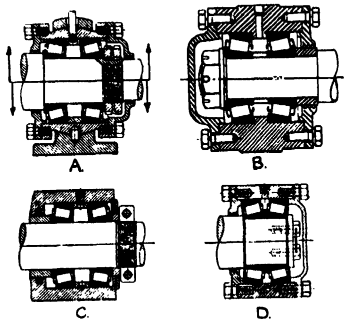

FIG. 6.—Double Bearing Mountings.

With long shafts or where thermal effects are present one double or two single bearings are mounted in separate housings at each end of the shaft. One pair axially locates the shaft, and the other pair is allowed to float. Housings can be rigid or self-aligning (see Fig. 6).

FOUR-ROW BEARING AND MOUNTING.

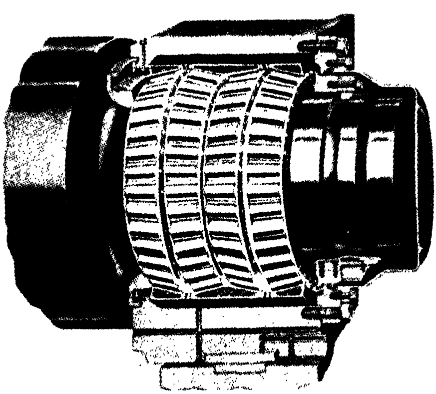

FIG. 7.—Four-row Tapered Roller Bearing Roll Neck Mounting.

Fig. 7 shows a roll neck mounting for the back-up rolls of a large 4-High rolling mill. The bearing has two double cones, one double cup and two single cups. Spacers are used between all cups and cones, ground to correct length during manufacture to give suitable running clearances in the bearing.

FLAT THRUST BEARING MOUNTING.

The following principles should be followed :—

(1) A radial bearing must be provided to centralise the revolving shaft.

(2) Races and rollers must be held in contact at all times.

(3) Faces supporting the races to be truly flat and square with axis of revolution, and robust enough to maintain this condition under maximum load.

(4) The outer rib of the revolving race to be mounted concentric with axis of revolution, and stationary race to have slight radial float to allow of self-centring.

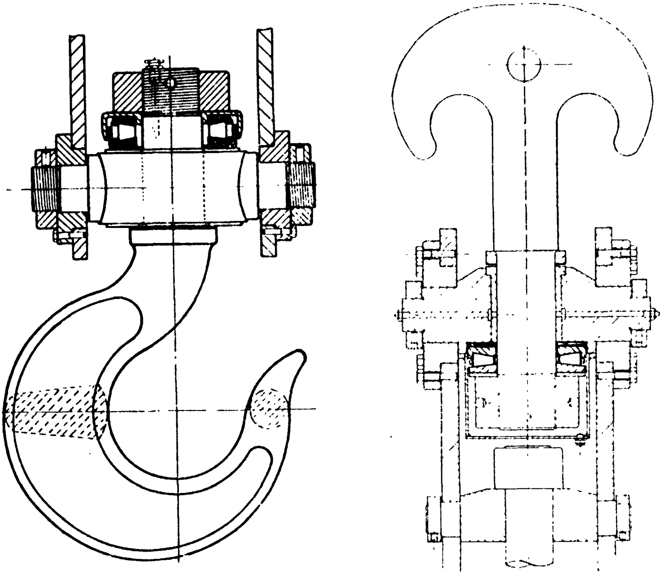

FIG. 8.—Crane Hook Mountings.

Fig. 8 shows (L.H.) light crane hook mounting, and (R.H.) shows 200 ton crane hook mounting.

LUBRICATION.

Oil or grease is used, the choice depending on bearing size, r.p.m., operating temperature, loading and working conditions.

(a) *Grease.*—Grease can be used for bearings of 6 in. o.d. up to 1,000 r.p.m. and for bearings between 6 in. and 12 in. o.d. up to 500 r.p.m., where temperature does not exceed 200° F. Housings should allow an adequate volume of grease on both sides of bearings and be fitted with grease nipple. Fill housing about ⅔ full. Grease lubrication often assists the seal under wet or dusty conditions.

(b) *Oil.*—Oil lubrication is usually necessary for high speeds. For oil bath lubrication maintain the level to immerse lower half of bottom roller under normal r.p.m., a visual indicator being provided.

With splash lubrication, provide collecting pockets above bearing (Fig. 9) with hole communicating to the SMALL-ends of the rolls, so that centrigufal force will assist circulation. Do not feed oil to the large ends of rollers as centrifugal force will resist circulation through the bearing.

With Timken automatic circulatory system, oil channels provide a complete circulatory path through and round each bearing. The oil volume and circulation holes should be as large as

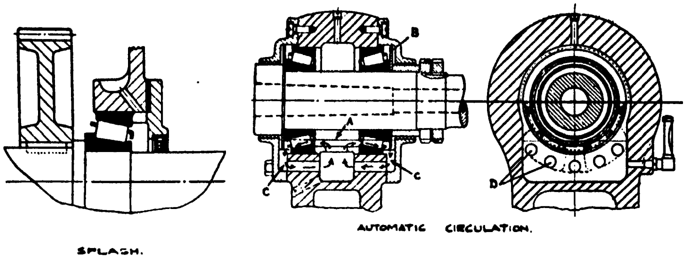

FIG. 9.—Lubrication Systems.

possible to obtain the maximum cooling effect (Fig. 9). This system is suitable for high speeds and saves cost of oil pump.

Other lubrication systems as the spray, oil pump circulation, and drip feed can be used.

Suitable oils are of the refined mineral type, free from acids and moisture and have a high flash point.

Light oils are used for high speeds, and *vice versa.*

Greases should be compounded from similar oils and high grade soap and contain no abrasive fillers, and oil should not separate on standing.

Water, acids, grit, etc., must be kept out of bearing housings to protect the highly finished bearings from corrosion and abrasion. Good seals are necessary, and can be of the rubbing or non-rubbing types.

Rubbing seals are available in a number of proprietary makes, the sealing elements being one or two rings of leather or synthetic rubber. Felt rings and stuffing boxes are also used.

Non-rubbing seals depend for their efficiency on close running clearances, labyrinths of various forms and flingers, combinations in many forms being possible. Some labyrinths are provided with nipples to ensure all spaces being filled with grease.

Applications of Tapered Roller Bearings.

There is practically no limit to the applications possible, these including automobiles, tractors, machine tools, locomotives, railway coaches, mining and steel works machinery, marine engines and thrust blocks, all types of war vehicles and vessels, gun mountings and fighting equipments, and all types of industrial machinery, etc.

Railway Axlebox and Crank Pin Applications, etc.

In addition to bearings, the Company manufactures railway axleboxes for steam, electric and Diesel locomotives, tenders, passenger coaches, electric motor coaches, wagons, etc. A few typical examples are shown (see Figs. 10, 11, 12 and 13). The boxes are made from high grade steel castings, arranged for Timken automatic oil circulation, and with hornguides faced with 11 to 14 per cent. manganese steel liners, which eliminate wear at these points.

Timken axleboxes are used on railways throughout the world, and require little attention beyond topping up with oil two or three times a year. Numerous examples are known of mileages considerably exceeding a million, with the bearings fit for further service. The starting effort is reduced by 85 per cent. compared with plain bearings, and the availability of locomotives and rolling stock greatly increased, as hot boxes are unknown, and oil consumption and maintenance costs are very low.

Timken Roller Bearings are also applied to the crank pins of steam locomotive driving axles, and to crossheads. Special lightweight reciprocating parts made from high quality alloy steel have been developed in connection with this type of application . which permits of better balancing of the locomotive, while reducing hammer blow at rail, and the destructive shaking and racking forces on the locomotive, and at the same time permitting an increase of 20 miles per hour to the maximum safe speed.

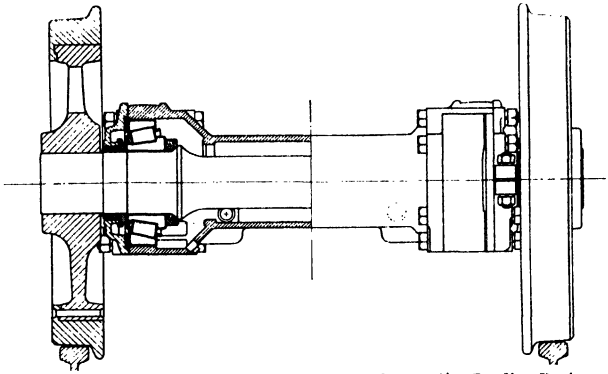

FIG. 10.—Solid type Cannon Axlebox—Steam Locomotive Leading Bogie.

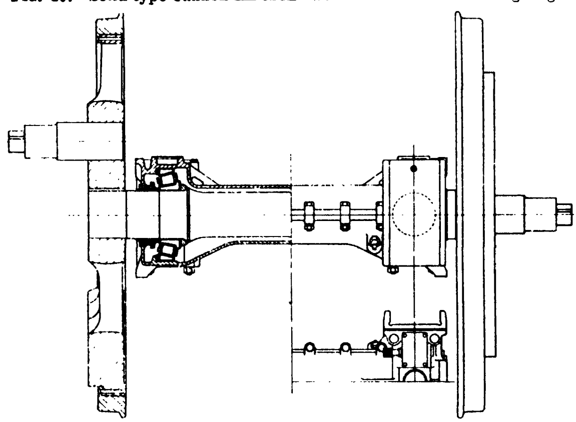

FIG. 11.—Split type Cannon Axlebox—Steam Locomotive Driving Axles.

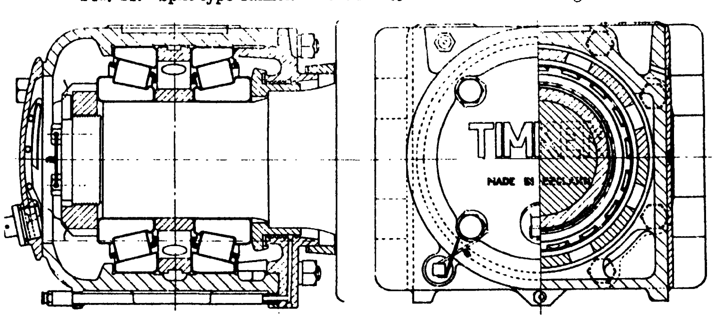

FIG. 12.—Outboard Axlebox—Steam Locomotive Trailing Trucks and Tenders.

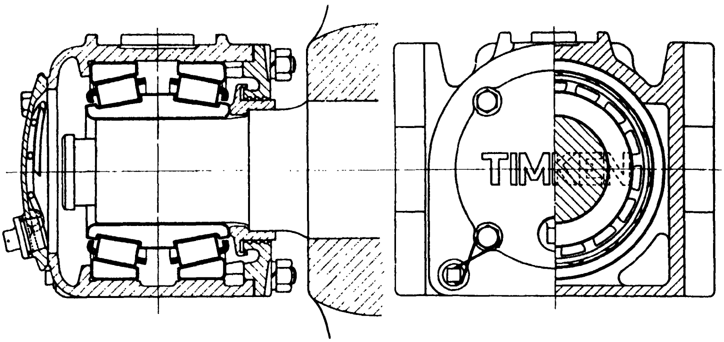

FIG. 13.—Outboard Axlebox—Electric and Diesel Locomotives, Motor Coaches, Passenger Coaches and Wagons.

ADDITIONAL DATA.

Designers and others requiring further information should refer to the technical literature (particularly the Timken Engineering Handbook) published by the Company, which includes also dimensions and data of the numerous types and sizes of bearings manufactured.

OIL RETAINING BRONZE BEARINGS.

(Bound Brook Bearings, (G.B.) Ltd., Trent Valley Road, Lichfield, Staffs.)

'Compo' oil-retaining bronze bearings are self-lubricating and suitable for practically all purposes for which ordinary machined bronze bushes and bearings are employed. These bearings are die-pressed from powdered metals and their composition is 90 per cent. copper and 10 per cent. tin—an alloy well known for its anti-frictional properties. They are porous to the extent of 25 per cent. to 35 per cent. by volume. The pores which are interconnected and distributed throughout the body of the bearing, are impregnated with a high grade mineral lubricating oil. As the result of capillary action between the oil and the cellular structure a thin film of oil is always present on the bearing surfaces. The application of bearing pressure, or rotational movement to the spindle, promotes a flow of oil from the pores to the bearing surfaces. This augmented oil film is maintained automatically during operation in proportion to any variation in the load, speed and temperature of the bearing.

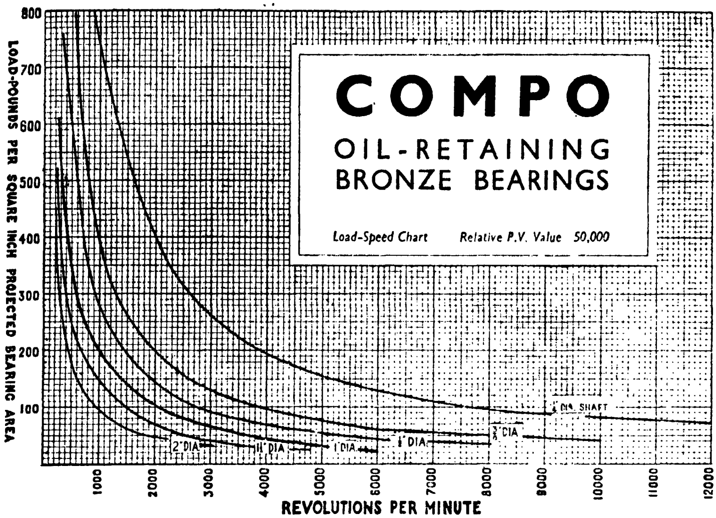
In calculating permissible loads, the conditions of operation, housing and its construction should be considered. Under ideal conditions of good heat dissipation or additional lubrication the PV factor of 50,000 utilised in the following chart may be exceeded. Where extreme conditions prevail as, for example, at high temperature, shock loading, dusty atmosphere, and lack of additional lubrication, the PV factor of 50,000 may be too high.

Because Compo bearings maintain an oil film between the shaft and the bearing, there is no theoretical limit of velocity. There are a number of installations in continuous day-to-day operation at 20,000 to 25,000 r.p.m. with small shafts. Where the PV factor approaches the maximum, bearing life expectancy will naturally be shorter than where the minimum factor is the basis. If, however, a provision is made to replenish the oil supply, the bearing will function indefinitely.

In general, it may be said that Compo bearings will carry a load equal to a normal bronze bearing, and because of their method of lubrication, will maintain an oil film to give a greater factor of safety.

In the following permissible load tabulation and chart, sufficient data are given to enable a rapid, general determination.

Velocity in Feet per Minute.	Permissible Loads.
Slow and Intermittent.	4,000 lbs. per sq. in.
25	2,500 " "
50–100	500 " "
100–150	325 " "
150–200	250 " "
over 200	per chart.



This chart may be used for general determination of permissible loads and allowable speeds for various shaft diameters. The figures are based on an empirical formula.

$$PV = 50{,}000.$$

in which formula P = the load per sq. in. of projected area.
V = shaft velocity in feet per minute.

Compo bearings are approved by the Air Ministry for use in aircraft for bearing loads up to 3,000 lb. per sq. in. for a slow and intermittent movement. Special impregnation with anti-freezing oil can be provided for applications involving very low temperatures.

Besides plain sleeve bearings, flanged bearings, spherical self-aligning bearings, thrust washers, strips and solids are available in sizes ranging from ⅛" diameter up to 3" diameter and up to 3" in length.

A comprehensive range of bearing sizes and lengths have been standardised for use with stardard bearings and shaft dimensions (see B.S.I. Specification 1131). Compo bearings are usually supplied to the finished dimensions required and ready for installing, hence no subsequent machining is normally required. The makers' recommendations should be followed where it is necessary to machine or ream the bearing surfaces of these bearings.

Compo bearings can be moulded directly to rubber, plastics and die-castings. In such cases, they are supplied without oil and impregnated after being moulded.

For the majority of applications the oil content of the bearings itelf is adequate to last the life of the machine. In special cases of high speed, high load or arduous conditions it is advisable to provide an additional supply of lubricant from a reservoir in the housing. The lubricant will then feed itself from the reservoir through the wall of the bearing to the bearing surface without the necessity of an oil-hole.

'Oilless' Graphited Bearings.

This is an accurately machined bronze bearing with grooves in it which are filled with a special graphite composition. The most suitable applications for the oilless bearings are those where oil cannot be employed and where conditions of load, high temperature or corrosive influences preclude the employment of an oil lubricated bearing.

This type of bearing is specially suitable for mechanisms on heating and drying ovens, also pulleys and rollers which have to operate at temperatures at which ordinary lubricants become carbonised. Other applications include bearings for chemical plant, food machinery and inaccessible parts of machine.

For continuous service a PV factor of 30,000 with a maximum speed of 500 ft. per minute or a maximum load of 1,000 lb. per sq. in. is suitable. For intermittent operation the PV factor may be as high as 60,000 with a load of 4,000 lb. per sq. in.

Bearing sizes ranging from ¼″ I/D up to 3″ I/D can be produced including flanged and self-aligning types.

Hoffmann Bearing Practice

(The Hoffmann Manufacturing Co., Ltd., Chelmsford, Essex.)

There is no need now-a-days to enlarge on the special place of ball and roller bearings in engineering practice. Their use in all mechanisms calling for free movement is taken for granted, and the general principles of their functioning are largely understood. Their purpose is to substitute rolling for sliding movement.

About the details of bearing application, some instruction may be helpful, as the rules governing the application of these bearings differ so much from those affecting plain bearings.

Basically, a plain bearing is merely a hole in a machine member in which a shaft revolves; or one in a wheel or pulley, carrying a shaft or axle on which it revolves. The necessary features are size, finish, correct alignment, provision for end location, and efficient means of lubrication. These essentials may be elaborated to any required extent as may be called for by the class of machine in question.

In ball and roller bearing practice things are different. Not only are such bearings required to operate with an almost total absence of power loss, but the rotating parts carried by them are to be retained in precise relation to one another throughout the machine's life.

There is still need for the above mentioned features, but in a greatly refined degree, and, in addition, complete protection from grit or dirt in any form. Sizes, finishes, etc., of the bearings themselves are the concern of their manufacturers, who provide full information on the tolerances of the bores and outside diameters, and make recommendations for seating and housing limits. These recommended figures provide suitable interference fits for rotating races of journal bearings, and push fits for stationary races.

It may be appropriate to give an extract from 'The Hoffmann Portfolio' on the various points to be kept in mind when mounting these bearings:—

'It should be remembered that all seatings on shafts or in housings must be perfectly cylindrical, that the surfaces forming abutments must be quite smooth and square with the shaft, and all recesses provided in housings for thrust races must be concentric with the shaft. Split housings should be avoided wherever possible, as a badly fitting cap may distort the races and cause local overload. Where conditions demand a split housing the cap must be registered or dowelled, and the seating for the bearing machined with the cap bolted in position. If the bearings are to be fitted in an aluminium housing it is desirable, where heavy loads are concerned, that the outer race should be housed in a liner of some harder metal. This is essential if the bearings are to be subjected to any considerable shock load.

'One of the most common causes of trouble with ball and roller bearings is creep or slow rotation of the races relative to the parts on or in which they are mounted. This creep cannot arise from friction in the bearings; it is purely the result of the conditions of working and can be eliminated if the following instructions are heeded.

'In thrust bearings creep is always due to the shoulders or abutments provided for the races not running perfectly square with the shaft. If the shoulder for the revolving race is not true it is the stationary race which creeps. Vice versa, if the stationary race is not square the revolving race will creep. Assuming the revolving race of a thrust to be out of square with the axis of the shaft, the whole of the load is carried by a small part of the race and consequently on one or two of the balls. As the shaft revolves this point of maximum load travels round the stationary race, giving it a tendency to creep forward on its seating. There is really an imperceptible wave movement, which becomes more pronounced the greater the inaccuracy. No matter how heavy the load or how high the speed, if the abutments or shoulders are square there should be no creep on thrust races.

'Whilst the underlying cause of creep (i.e., the travelling of a point of maximum load round the race) is precisely the same in journal bearings, it must be dealt with in an entirely different way. The conditions to be fulfilled by a journal bearing are such that the load can never be evenly distributed round the race. Taking the ordinary horizontal revolving shaft with a downward pressure due to the weight supported, the load will always be on one portion (of about 120 degrees) of the outer race, whilst on the revolving race this point of maximum load will be constantly changing as the shaft rotates. It will therefore be clear that it is the rotating race of a journal bearing which will have the tendency to creep.

'There should be no tendency for the stationary race of a journal bearing to creep, and it is for this reason that the stationary race of a ball journal bearing is chosen to be free endways to

permit of its aligning itself opposite the revolving member and thus preventing permanent end thrust. Where such a tendency to creep is pronounced in a stationary journal race, it is an indication that there is a recurrent change in the direction of the load, such as might be caused by lack of balance in the revolving mass. If the point of greatest load travels round the stationary race, the latter will roll round its seating, and at each complete revolution creep or lag will result to the extent of the difference in length of the two circumferences.

'The effect on the bearings of a machine resulting from lack of balance is not always fully appreciated. To secure steady running with a minimum of vibration, high-speed machines should be in balance at their normal rate of running—static balance is not sufficient to give the best results. In those cases, such as an eccentric, where an unbalanced load is inevitable, a roller journal bearing should be employed and both races made an interference fit.

'Given reasonable care in the machining of the seatings and in the fitting of the bearings, there is no difficulty whatever in avoiding 'creep' even with the heaviest loads. Keys and similar devices are quite unsuccessful and unnecessary, and quickly wear away under the constant chafing. They also introduce the risk of distortion of the races.'

This book, The Hoffmann Portfolio, gives much useful bearing information. Differing types of closure designed to give ample protection under varying conditions of service are illustrated. There is a long article on 'Methods of Calculating Loads on Bearings.' But the greater part consists of illustrated specimen mountings of ball and roller bearings in a wide variety; and these serve to show on the one hand the various points that need attention, and, on the other, the simple means by which all requirements may be met. For it should be emphasised that success in the use of these bearings is not difficult of attainment. The underlying principles are few and simple, and the machine equipped with intelligently selected and properly mounted ball and roller bearings is not only a more efficient machine at the outset—it remains so throughout its useful life.

But these subjects appeal more particularly to machine designers and makers. For machine users, who are concerned about the efficient running of the bearings. An article on 'Lubrication and Protection' is of special interest. It says, *inter alia* :—

'Oil is undoubtedly the most efficient lubricant, but the natural advantages offered by grease, which possesses both lubricating and permanent coating properties, render this form particularly suitable for use with ball and roller bearings. Grease also makes an effective closure between the shaft and housing, thus retaining the supply and excluding all moisture and dust, whereby the utmost economy and general cleanliness in operation are insured. The use of grease as a lubricating medium is to be recommended wherever practicable.

'A suitable grease should have a mineral base (lime or soda), but should contain no mineral acid, and be free from alkali or foreign matter. No filling agent should be employed, for the presence of such substances as graphite, talcum, etc., although in an extremely fine state of subdivision will give rise to lapping of the bearing parts, and so cause wear. Stability is of the utmost importance and the grease should show no tendency to gum, thin out, or separate into its constituents on standing or in service.

'For normal conditions, a good quality lime soap grease of medium consistency, and having a melting point of approximately 200° F. is recommended, and such a lubricant should withstand a continuous running temperature of 100/110° F.

'For conditions involving high speed or high temperature, a soda soap grease should be used. These lubricants usually have a melting point of 300/350° F. with a proportionately higher consistency, and considerable care should be exercised in their selection to secure the best results. The softer grease of this type will be found suitable for working temperatures up to 150° F., whilst those of higher consistency, which are usually termed high melting point greases will operate satisfactorily at temperatures up to 220° F.

'Oil lubrication should be applied in the following cases :—

(1) For light running parts where the resistance must be reduced to an absolute minimum.

(2) Where the bearings are completely enclosed in casings containing other parts for which oil lubrication is necessary, e.g., gear boxes, or when required to work in conjunction with plain bearings.

(3) Where the speed is unusually high, or the maximum is to be obtained. (For the above, use good quality mineral oil of light to medium viscosity.)

(4) For temperature conditions in excess of 220° F. (Use steam cylinder oil.)'

Attention to the above details is amply repaid. Proper mounting, proper protection, and proper lubrication will preserve ball and roller bearings almost indefinitely.

'Oilite' Self-Lubricating Bronze Bearings.

(*Manganese Bronze and Brass Co., Ltd., Handford Works, Ipswich.*)

'Oilite' Self-lubricating Bronze Bearings (oil-retaining bearings) are a product of powder metallurgy being manufactured from copper and tin powders, die-pressed and alloyed to form superior tin bronze with a microporous structure capable of retaining 30 to 35 per cent. of high-grade mineral lubricating oil. They are produced to precise dimensional accuracy and in addition to their good physical properties they possess the ability to supply a regulated flow of oil to the

journal according to the varying load, speed and temperature demand, and of maintaining at all times a uniform film of oil at the surfaces re-absorbing the oil as the load or temperature returns to normal.

For the majority of applications, the original oil content of an 'Oilite' Bronze Bearing is sufficient to outlast the life of its component, but where high speeds or other special conditions prevail, supplementary lubrication may be advisable which can readily be provided by means of a reservoir in the housing, so that as the original oil is used up, the bearing is replenished by capillary action, from the reservoir.

These bearings are suitable for practically all applications where ordinary bronze bearings are used but with the added advantages of a greater factor of safety and no lubricating problems to the user. They may be used for applications ranging from slow or intermittent movement up to high-speed rotation, and have been approved by the Air Ministry for loads of up to 3,000 lb. per sq. in. on oscillating movements, while in actual service they have proved successful at loads of over 4,000 lb. per sq. in. on slow or intermittent movements; at the other extreme they have been employed with good results in conjunction with spindles running at 30,000 r.p.m.

Tests are being carried out continuously under varying loads and speeds, and the following are actual results obtained, employing hardened and ground journals loaded on the lower surface and using no other lubricant than that originally contained in the test bearings.

Particulars of Test.		No. 4/3.	No. 1/12.
Bearing dia. × bore × length	(inches)	$1 \times \frac{3}{4} \times 1$	$1\frac{5}{8} \times 1\frac{1}{4} \times 1\frac{1}{2}$
Journal running speed	(r.p.m.)	2,100	1,100
Bearing pressure	(lbs./in.^{2})	80	60
Total running period	(hours)	1,500	4,010
Percentage oil content—initial	(by vol.)	28·0	27·3
„ „ „ —final	„	22·7	20·6
Total wear on bearing	(inches)	0·0005	0·0012
„ „ journal	„	nil	0·0002

The tests were concluded at the end of the predetermined period and not because of failure, for it will be observed that there was an adequate supply of oil still available.

The load carrying capacity of a bearing is a function of speed and load, and is a product of the two variables—feet per minute and pounds per square inch—usually expressed as P.V. For 'Oilite' this P.V. value for normal conditions of operation and without supplementary lubrication, is 50,000, but must be modified where shock loading is encountered and can be substantially increased with supplementary lubrication.

These bearings can be supplied for operations at temperatures down to minus 60° C. and up to 100°C. and impregnated with suitable lubricants to withstand such conditions. They are delivered fully impregnated and in a finished state, ready for assembly without any subsequent machining; the 'Oilite' Size List gives full particulars of the range of types and sizes available, including cylindrical, flanged, thrust and self-aligning bearings and washers, and, in addition, solid round rods, tubular blanks, rectangular strips and plates from which customer can machine special requirements.

Continued expansion in research and investigation in the field of powder metallurgy has produced new products including 'Oilite' bronze in the form of solid and cored bar and plate stock for machining, 'Oilite' lead bronze for seal rings and similar applications, and 'Oilite' super load, a material for bearings subject to extreme pressures, heavy shock load and severe atmospheric conditions. It should be noted that these new products possess similar self-lubricating (oil-retaining) properties as the original 'Oilite' Bronze.

A further new product is the 'Oilite' sintered metal filter, suitable for all types of filtration, flame arrestors, etc., possessing satisfactory physical strength properties. Structural parts in sintered iron and super load are now being developed where oil retaining properties are not a requirement, but where denser structure is necessary to give desired strength and to eliminate expensive machining operations.

R. & M. BALL AND ROLLER BEARINGS.

(Ransome & Marles Bearing Co., Ltd., Newark-on-Trent.)

The wide range of R. & M. ball and roller bearings and the multiplicity of sizes, offers a comprehensive range of bearings suitable for every application. These are fully described in the catalogues, which will be gladly supplied on request by the makers. The sectional drawings

shown below illustrating various types of bearings, and indicating their suitability for thrust or journal load, are only inserted as a guide.

In the development of these various series of bearings Ransome & Marles Bearing Co., Ltd., have played a major part, and the adaptability of some of the series to speeds as high as 90,000 r.p.m. is due to the investigations which this firm have carried out. High speeds such as that quoted are only obtainable by the use of carefully balanced cages made of lighter materials than is the normal accepted practice. The experiments revealed that success was obtainable when cages made of duralumin or bakelite were employed.

Additionally, although the normal tolerances for ball or roller bearings are fine, for these exceptionally high speeds the limits of accuracy must be approximately half those accepted for standard bearings. This, together with methods of preloading the bearings, whether this is carried out in the bearing itself, or within the application, has resulted in the wide adoption of R. & M. bearings for grinding spindles and other machine tools, where precision and high speeds are essential to modern practice.

Another feature of R. & M. bearings is their ability to withstand exceptionally heavy loads Rolling mills, lifting bridges and rolling stock, being a few instances where these bearings are working under arduous conditions, and are in many instances subjected to severe shock loads.

Experience shows that wherever a shaft revolves or oscillates R. & M. bearings can be used to advantage, and this firm would be pleased to demonstrate this by supplying, on receipt of details, application drawings showing guaranteed arrangements. This service is, in common with all the technical service of Ransome & Marles Bearing Co., Ltd., placed at the disposal of users without obligation.

TYPES OF R. & M. BEARINGS.

SINGLE-ROW BALL JOURNALS

For journal loads but will withstand end thrust.

BALL JOURNALS WITH SHIELDS

A range of ball journal bearings are supplied fitted with shields to one or both sides of the bearing.

BALL JOURNALS WITH SEALS

A range of ball journal bearings are supplied fitted with seals to one or both sides of the bearing.

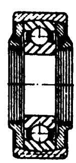
DOUBLE-ROW BALL JOURNALS

(Rigid type)

For journal loads.

DOUBLE ROW SELF-ALIGNING BALL JOURNALS

For journal loads where misalignment is present.



SELF-ALIGNING BALL JOURNALS IN HOUSINGS

For journal loads but will withstand end thrust.

Other types can be supplied fitted with spherical seatings.

SINGLE-ROW DOUBLE-PURPOSE BEARINGS

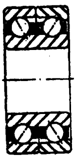
For combined journal and thrust loads (thrust in one direction only).

DUPLEX DOUBLE PURPOSE BEARINGS

For thrust in either direction—can be used for combined journa and thrust loads.

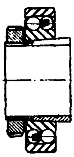
Types of R. & M. Bearings continued on page 1144.

TYPES OF R. & M. BEARINGS—Contd.



DOUBLE-ROW
DOUBLE-PURPOSE BEARINGS

For combined journal and thrust loads (thrust in either direction).



ADAPTER BEARING
DOUBLE ROW BALL

For journal loads.

Other types can be supplied fitted with adapter sleeves.

ROLLER JOURNAL
BEARINGS

(Two shoulders in inner race and plain outer race.)

For journal loads only.

ROLLER JOURNAL
BEARINGS

(One shoulder in outer and two shoulders in inner race.)

For journal loads and location duty in one direction only.

ROLLER JOURNAL
BEARINGS

(With lip and loose side plate on outer and two lips on inner.)

For journal loads and location duty in either direction.

ROLLER JOURNAL
BEARINGS

(With two shoulders in outer and plain inner race.)

For journal loads only.

ROLLER JOURNAL
BEARINGS

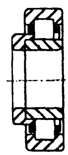
(Two lips in outer and one lip on inner.)

For journal loads and location duty in one direction only.

ROLLER JOURNAL
BEARINGS

(With two lips in outer and one lip and loose side plate on inner.)

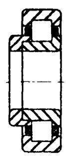
For journal loads and location duty in either direction.



ROLLER JOURNAL
BEARINGS.

(Two lips in outer, parallel inner and flanged side plate.)

For journal loads and location duty in one direction only.



ROLLER JOURNAL
BEARINGS

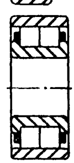
(Two lips in outer, one lip and flanged side plate on inner.)

For journal loads and location duty in either direction.

ROLLER JOURNAL
BEARINGS

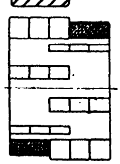
(With two lips in outer and two lips on inner.)

For journal loads and location duty in either direction.



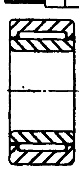
DOUBLE-ROW
ROLLER BEARINGS

For journal loads only.



ROLLER BUSHES

For journal loads only.



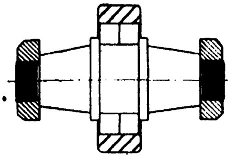
NEEDLE ROLLER
BEARINGS

For journal loads only.

(Needle rollers can also be supplied in cartridge housings.

Types of R. & M. Bearings continued on page 1145.

TYPES OF R. & M. BEARINGS—Contd.



ROLLER BEARING CRANKPINS

For internal combustion engines.

SELF-ALIGNING ROLLER BEARINGS

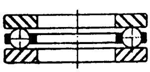
For journal loads where misalignment is present. Other types can be supplied fitted with spherical seatings.

SELF-ALIGNING ROLLER JOURNALS IN HOUSINGS

For journal loads where misalignment is present and for location duty in either direction.

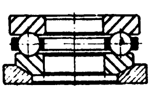
SINGLE THRUST BEARINGS

For thrust in one direction.



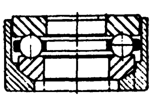
FLAT TRACK THRUSTS

For thrust in one direction.



SINGLE SPHERICAL THRUSTS

For thrust where misalignment is present.



SINGLE SPHERICAL THRUSTS IN HOUSINGS

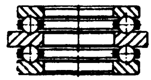
For thrust where misalignment is present.

DOUBLE ROW BALL THRUSTS

For exceptionally heavy loads.

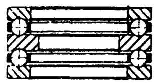
ROLLER THRUST BEARINGS

For exceptionally heavy duty at slow speeds.



DOUBLE THRUSTS

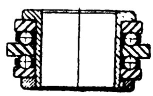
For thrust in either direction.



DOUBLE THRUSTS

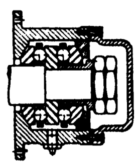
(centre washer locating).

For thrust in either direction.



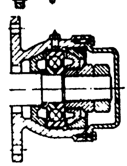
DOUBLE THRUSTS WITH SLEEVES

For thrust in either direction.



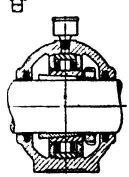
DOUBLE THRUSTS IN HOUSINGS

For thrust loads in either direction.



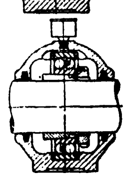
DUPLEX DOUBLE PURPOSE BEARINGS IN HOUSINGS

For thrust in either direction.



ROLLER LINESHAFT BEARINGS

For the heaviest loaded lineshafting.



BALL LINESHAFT BEARINGS

For light or medium loaded lineshafting.

The Selection of Ball and Roller Bearings.

(The Skefko Ball Bearing Co. Ltd., Luton, Bedfordshire.)

In selecting a bearing for a particular application it is necessary to have a thorough knowledge of the conditions existing in each specific case and of the characteristics of the different bearing types. Although no hard and fast rules can be laid down concerning the matter of bearing selection certain observations can be made about selection with regard to type. For lightly loaded high speed applications, ball bearings are generally most suitable. For large and heavily loaded applications, only roller bearings are satisfactory. If there is any likelihood of misalignment between shaft and bearing housing, a self-aligning bearing is desirable. If completely free axial displacement of the shaft between certain limits is necessary, a cylindrical roller bearing should be used. For applications where high speeds and relatively heavy thrust loads are encountered, a deep groove ball bearing may be the best choice. Used extensively in the automobile industry, taper roller bearings offer certain advantages in dealing with combined radial and thrust loads, especially where shock loads are met with.

The most important factors influencing bearing selection are discussed briefly in the following paragraphs.

The magnitude of the load, together with considerations of shock load and available space, has a primary influence on the bearing size, and also influences to a great extent the choice of bearing type. For small loads a ball bearing is generally used; for heavy loads a roller bearing is frequestly the only type possible. In different bearing types the ratio of radial and thrust load capacity varies considerably; selection must therefore be made with due regard to direction of loading. For pure radial load, any radial bearing could be used to advantage, and selection would then be made after consideration of other factors. With combined radial and thrust loads, after determining the magnitudes of the respective loads, consideration can be given to whether a single bearing can carry the combined loads or whether a bearing should be fitted to deal with each load component.

The speed of rotation in most cases only influences the bearing selection if it is unusually high. The speed at which a bearing may be run is determined, as a rule, by the temperature rise which is dependant on several factors. Inasmuch as radial ball bearings and cylindrical roller bearings have very low frictional characteristics under radial load, they can be used at higher speeds than other types. In addition, the material and design of the cage has some influence at high speeds. Therefore, in exceptional cases it may be necessary to employ cages of special material and design.

Fits, mounting and maintenance do not affect bearing selection in a direct way, but indirectly are of importance. For example, if the shaft of an electric motor expands and contracts owing to any considerable temperature variation, and the operating conditions are such that the bearings require a tight fit in the housing as well as on the shaft, one bearing must be of a type that permits axial movement. A common arrangement for such an application is a deep groove ball bearing at one end, and on the other end of the shaft (usually the drive end) a cylindrical roller bearing with rings that can be displaced relatively to each other. If the machine is of a type that is frequently assembled and dismantled, open bearing types such as cylindrical roller bearings, taper roller bearings or separable ball bearings (magneto bearings) may be necessary. In addition, tapered adapter and withdrawal sleeves help to solve some mounting problems. From the practical point of view, machines that operate under conditions of infrequent lubrication and inspection, should preferably be fitted with ball bearings as they are usually less demanding in these respects.

Standard bearings should be adopted as far as possible, and special types avoided. Apart from questions of cost and delivery time, special bearings present a very real difficulty when replacements become necessary.

The range of SKF bearings is such that the correct type and size of bearing for practically every application can be supplied. In the following are mentioned the types in most common use, together with brief details of the conditions for which they are most suitable.

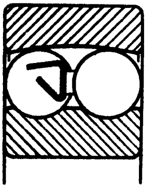


Fig. 1.

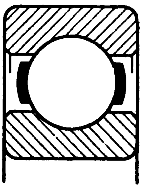

Fig. 2.

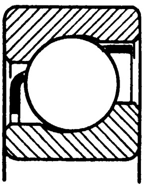

Fig. 3.

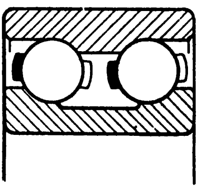

Fig. 4.

The Double Row Self-Aligning Ball Bearing (fig. 1) has two rows of balls which run on a common spherical track in the outer ring. This design allows the inner ring, together with rolling elements, to align itself freely about the bearing centre, and to accommodate a certain degree of misalignment caused by frame distortion and shaft deflection.

The Deep-Groove Ball Bearing (fig. 2) gives the maximum possible support to the balls by virtue of its deep uninterrupted race grooves, thus providing comparitively great radial and thrust load carrying capacity. This bearing is suitable for applications where combined loads within its capacity are encountered, for high speed work, and as a locating bearing.

The Single-Row Angular Contact Ball Bearing (fig. 3) has large diameter balls, a definite contact angle and high shoulders on the rings, giving good radial and one-direction thrust capacity. It can be employed with advantage where the thrust is greater than can be dealt with by a single-row deep-groove bearing, but where the use of a taper roller bearing is hardly justified.

The Double-Row Angular Contact Ball Bearing (fig. 4) is similar to the single-row type and is characterised by its large diameter balls, high shoulders on the rings and contact angles giving maximum radial and thrust capacity in both directions. It is outstandingly suited to positions where radial and axial rigidity is required.

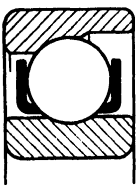

FIG. 5.

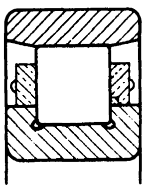

FIG. 6.

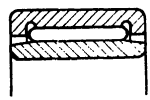

FIG. 7.

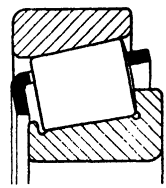

FIG. 8.

The Separable Ball Bearing (fig. 5), or magneto bearing, is a single-row type with a somewhat shallower groove on the inner ring than the deep-groove ball bearing. The outer ring has only one shoulder so that the bearing is ' open ' or separable. The bearing capacity is rather low but it offers certain advantages for easy mounting in magnetos, etc.

The Cylindrical Roller Bearing (fig. 6) has large diameter rollers, with rings having high guiding flanges on the inner or outer ring. It is suitable where radial loads are heavy and where end thrust is taken up separately. Certain types are available with lipped outer ring for location purposes where the axial load is small and does not warrant the use of a separate thrust bearing.

The Needle Roller Bearing (fig. 7) can be considered as a variant of the cylindrical roller bearing. Though less efficient than normal cylindrical roller bearings, this type may be used with advantage particularly where there is little room diametrically.

The Taper Roller Bearing (fig. 8) has straight tapered rollers, a sphered surface on each roller head, and a corresponding spherical flange face on the cone ensuring perfect guiding of every roller. This bearing is suitable for dealing with combined radial and thrust loads where good alignment is assured.

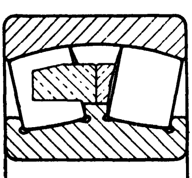

FIG. 9.

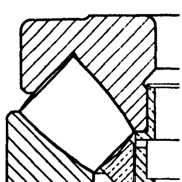

FIG. 10.

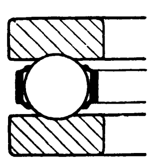

FIG. 11.

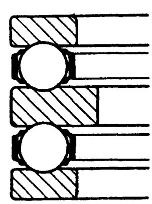

FIG. 12.

The Spherical Roller Bearing (fig. 9) is a double-row design, both rows of rollers having a common spherical track in the outer ring, so that the bearing is fully self-aligning in the same manner as the self-aligning ball bearing. Since the load is always evenly distributed between the two rows of rollers, and both rows have a maximum number of rollers, this bearing has the greatest possible capacity in a given space. It is suitable for the heaviest radial loads, has a considerable thrust capacity, and can withstand very severe shock loads ; it is, in short, the pre-eminent bearing for all heavy duties.

The Spherical Roller Thrust Bearing (fig. 10) is a variant of the spherical roller bearing with an exceptionally large contact angle. Unlike most thrust bearings it is fully self-aligning within itself, and is also capable of carrying a degree of radial load. It is the ideal bearing for heavy thrust duty.

The Single Thrust Ball Bearing (fig. 11) is designed for dealing with end thrust in one direction only, and is used in cases where the axial load is too heavy to be carried by a radial double-purpose bearing. Certain types are made with spherical seatings and seating rings to compensate for errors of alignment.

The Double Thrust Ball Bearing (fig. 12) is similar to the single thrust ball bearing, but can carry thrust in either direction. Again, types are made with spherical seatings and seating rings to compensate for misalignment.

Practically every bearing problem can be solved satisfactorily by careful selection from the SKF range of ball and roller bearings of a type and size to suit the conditions of load and speed. Engineers are aware, however, that the correct choice of bearing does not in itself ensure the high efficiency and long bearing life it is possible to obtain. Shaft and housing designs, limits and fits, methods of handling and fitting, lubrication, and other relative factors, must be thoroughly understood and the knowledge applied

SECTION XX

PART II

Lubricating Oils and Lubrication.

Graphite Lubrication.

(*Graphite Products, Ltd., 52 Battersea Church Road, S.W. 11.*)

Graphite is, chemically, carbon, but unlike the diamond, which is also carbon, the crystalline structure consists of hexagonal plates, which readily break apart, forming flakes. These flakes will range from ¼-inch or more across, when exceptionally large, to those of ultra-microscopical dimensions. Generally it may be said that under suitable grinding conditions the flaking process will continue indefinitely.

If graphite is squeezed between two adjacent surfaces, such as a journal and a bearing, the smaller flakes will be caught and fixed in the interstices, leaving the larger flakes to form a highly polished and unctuous surface. Conventionally, it may be illustrated as in figs. 1 and 2 (p. 1149).

From observation of the diagrams it is clear:

(1) That in the case of fig. 1 *starting friction is heavy.*
(2) That if pressure between faces is sufficient *seizing will take place.*
(3) The presence of oil or grease in the interface *does not necessarily prevent these results.*
(4) The presence of flake graphite forms a *smooth, greasy* and *unctuous surface.*
(5) *Starting friction is very small.*
(6) Prevents *metallic contact, so seizing cannot take place.*
(7) *Stops wear of metal.*
(8) If oil is used with the graphite *less oil is needed.*

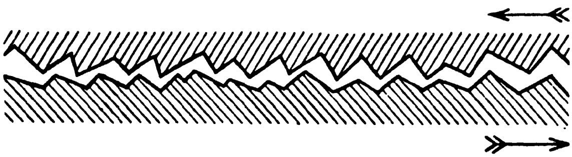

FIG. 1.

Another advantage of graphite not shown by the foregoing, is that graphite has a conductivity of 0·0117 against mineral oil of 0·0003, so that:

(1) Bearings are kept cool.
(2) Greases which without graphite might melt and flow out of the bearing are prevented from doing so by addition of graphite. It should be added that capillary attraction between the flakes also helps to this end.

Proof in experiments of these points is of interest:
Friction between dry, smooth and clean metal surfaces before and after graphiting.

STEEL AND BABBITT METAL.	
Before graphiting	$\mu = 0{\cdot}515$
After graphiting	$\mu = 0{\cdot}140$
STEEL ON STEEL.	
Before graphiting	$\mu = 0{\cdot}365$
After graphiting	$\mu = 0{\cdot}157$

Authority: Koethen.

These are very high coefficients in any case, but the reduction is remarkable. It must be remembered, too, that, except where oil or grease are impracticable, dry graphite is not used alone but always as a means of improving the properties of the usual lubricants.

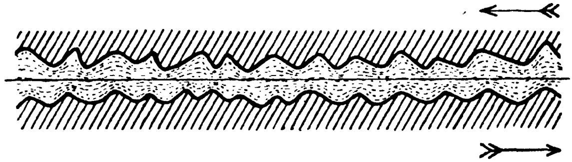

FIG. 2.

The effect of the use of 'Foliac' Lubricating Flake Graphite with a lubricating vehicle such as an oil or grease is:

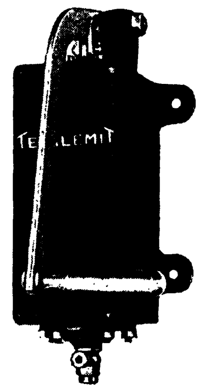
(1) To increase the efficiency of the lubricant and reduce friction. (10 per cent. to 40 per cent. reduction of friction are not unknown.)
(2) To increase the permissible bearing pressures. (Sometimes as much as 100 per cent.)
(3) To enable easy starting.
(4) To enable less lubricant to be used for a given service.

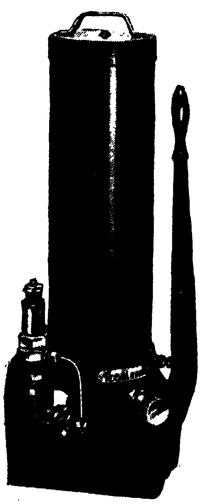
The proportions of 'Foliac' Pure Flake Lubricating Graphite to oils and greases to give the optimum results will vary considerably, and consequently it is advisable for those who desire the best results to buy 'Foliac' Graphite Lubricants, which are made for all classes of work, rather than buy the graphite alone, unless they have had previous extensive experience in the making of graphited lubricants.

Tecalemit 'Bijur' Metered Lubrication System for Use with Oil.

(Tecalemit, Ltd., Great West Road, Brentford, Middlx.)

This is claimed to be an essentially up-to-date method of central lubrication for almost any type of machine. Its features are characteristic of Tecalemit industrial equipment and comprise a 'Bijur' oil pump, hand operated or driven from the machine itself, and a single supply line which can distribute to a considerable number of points fitted with meter valves of widely varying capacities to satisfy the requirements of individual bearings. Installation is thus simple and inexpensive. The correct oil film is maintained automatically, making this system particularly applicable to textile and other plant where over-lubrication is detrimental, yet ensuring that the bearing furthermost from the pump is fully supplied. Clean oil of practically any viscosity may be used with 'Tecalemit-Bijur' equipment without adjustment, metered lubrication being automatically maintained under all operating conditions.





Tecalemit 'Line-o-Matic' Lubrication System for Use with Grease.

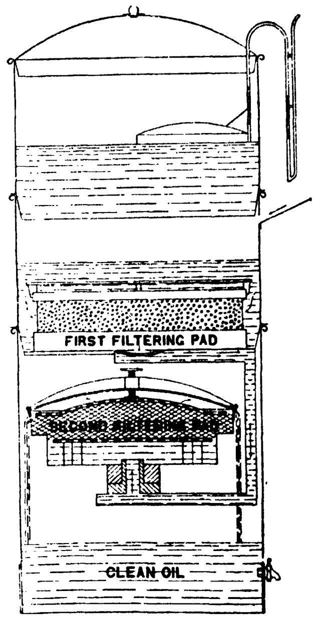
The makers state that this is a simple centralised system applicable to almost any machine requiring heavy oil and soft grease lubrication. The essential components include the Line-o-Matic Pump, the single supply line and the bearing automatic injection. The pump can be manual, as illustrated, or an automatic power-driven model. The single supply line provides easy and economical installation, and is capable of distribution to a considerable number of bearings. The automatic injector situated at each lubrication point is calibrated to supply the correct injection to suit individual requirements, thus the possibility of excessive lubrication or partial-starvation are each eliminated. The Line-o-Matic system, it is claimed, ensures complete lubrication of the machine in one pump-cycle, giving both positive assurance and complete safety to operators.

Recovery of Lubricating Oil.

(*A. C. Wells & Co., Ltd., Mount Street, P.O. Box 5, Hyde, Cheshire.*)

These filters consist of three compartments, any of which can be readily removed from the other to facilitate cleaning.

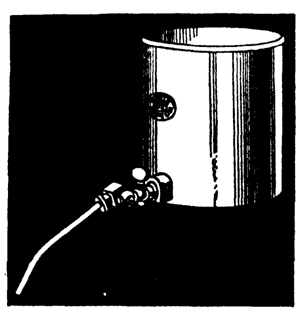
The top chamber receives the dirty oil, which after admission is allowed to settle for about a day, the time varying with the degree of foulness attained by the oil. The top chamber is provided with a floating syphon which when set in operation delivers the settled oil drop by drop into the second compartment, whence it passes by gravity through a special filter pad into the lowest compartment. The descending oil is collected off the underside of the filter pad in the second stage and led into a tube which terminates in a further filter pad. This cleans the oil by upward filtration, the recovered oil falling into the bottom of the third, or lowest, compartment, whence it is drawn off for re-use as required. By heating the oil with steam coils or electric heaters the capacity of the filter can be practically doubled.



Wells' Lathe Cans.

(*A. C. Wells & Co., Ltd., Mount Street, P.O. Box 5, Hyde, Cheshire.*)

Wells' lathe cans are available in two sizes: 2-pint and 1-gallon. Made of iron, and soundly constructed, these lathe cans will give years of hard service. Both sizes are fitted with brass universal fittings.



SECTION XXI

PART II

Belting—Belt Driving—Clutches.

Belting.

R. & J. Dick, Ltd., Greenhead Works, Glasgow, S.E.)

During the present restriction of the supply of raw materials, it is of the utmost importance that the care and maintenance of belting should be attended to.

The following points should enable belt users to get longer and more useful life from their belting.

Never allow dirt or other matter to collect on the surface of the belt. Such dirt forms into lumps, tearing or distorting the driving face of the belt, and preventing it from forming proper contact with the pulley.

Care should be taken to prevent oil from getting at the belt. It will cause loss of power by slip, and it is particularly harmful to Balata and cotton belts, tending to separate the plies. It will also rot a leather belt and rapidly lessen its efficiency.

Chemical action caused by bad air in close and badly ventilated rooms will damage Balata belts. An occasional application of castor oil used sparingly on both sides of the belt will combat deterioration from this cause.

Belting should not be run too tight, it reduces power and wears it out.

See that belt is running true, if not check up the alignment of shafting and pulleys.

Never run a thick belt over a small diameter pulley ; thin belts grip best and transmit more power.

An overloaded belt will cause it to slide from side to side of pulley. Cure—thicker or wider belt, or fit extra belt on top of existing one.

Slip is shown by polished pulley. In the case of a Balata belt a few drops of castor oil applied to the face of pulley will probably cure this. If the belt still slips it should be shortened.

Clutches.

Coil Clutch.

(The Coil Clutch Co., Ltd., Phœnix Works, Johnstone, Renfrewshire.)

The clutch shown in fig. 1 consists of a bushed driving plate (*c*) mounted on a shaft and having lugs cast on its face to engage the transmitting coil (*a*). A drum (*b*) of chilled material

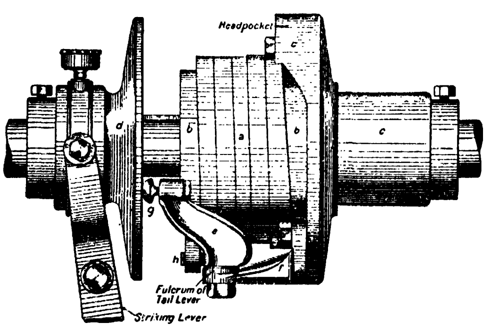


FIG. 1.

is keyed to the shaft adjacent to the driving plate. The transmitting coil (*a*), of special steel, having a highly-finished internal surface, is mounted on the drum and has one end engaged with the driving plate lugs, whilst the other is free to be operated. A sliding member (*d*) is mounted

on the shaft beyond the drum, its function being to pull the free end of the coil through a steel lever (*e*), which is pivoted on an extension of the driving plate (*c*), and engages the free end of the coil.

In engaging the clutch, the plate (*d*) is moved towards the drum, thereby tilting the lever (*e*) and tightening the free end of the coil, which is contracted and gradually tightens on to the drum (*b*), causing the different members of the clutch to be locked together. The action is similar to that of a man tightening the free end of a rope on a revolving capstan.

The clutch, made by the Coil Clutch Co., Ltd., Johnstone, is simple in construction and compact, and is used on transmissions such as :—haulage gears, cranes, rolling mills, wire and tube drawbenches, and bending rolls and presses.

Brakes and Brake Linings.

'FERODO' BRAKE LININGS.

(*Ferodo Ltd., Chapel-en-le-Frith, Stockport, England.*)

Friction linings can be divided into two main types, cotton and asbestos base. The latter can again be sub-divided into metallic and non-metallic.

Ferodo Fibre linings are produced from a solid woven cotton base, specially impregnated; this treatment imparting exceptional qualities of wear resistance and a high coefficient of friction to the finished lining. Impregnation also raises the naturally low resistance to heat of the cotton base to the maximum recommended operating temperature of 220° F. The value of the coefficient of friction for design purposes is 0·5. This lining can be supplied up to 18 ins. wide and from ⅛ in. to 1 in. thick. It is applicable to all types of brakes and cone clutches in engineering practice, subject to the temperature limitation already specified.

Ferodo Fibre H.D. friction lining is similar to the material described above, but will satisfactorily resist working temperatures up to 350° F. Its coefficient of friction for design purposes can be taken at the same value of 0·5 and it is manufactured in the same range of sizes. It is, however, a rigid product and therefore cannot be supplied in roll form. For the same reason Ferodo Fibre H.D. linings must be formed to the final radius during manufacture and this is particularly necessary when this material is fitted to post brakes where each end is given a comparatively sharp reverse bend for anchorage purposes.

Asbestos base, metallic and non-metallic, linings are available in a variety of types to meet the requirements of particular applications.

Ferodo Bonded Asbestos lining is produced from solid woven asbestos, brass wire being introduced during weaving. It is bonded by an infusible process which gives it its characteristic coefficient of friction and wearing qualities. The coefficient of friction for design purposes should be taken as 0·33. It is a lining suitable for running against all types of cast-iron and against steels having a Brinell hardness of 200 and over. It is available in thicknesses from ⅛ in. to 1 in. and in any width up to 18 ins. and in rolls up to 50 ft. lengths or in die-pressed segments. These latter segments have the same friction properties as the roll material from which they are manufactured, but, as they are highly compressed, they give a considerable increase in lining life and the segments are mechanically stronger and more rigid. A large range of sizes of die-pressed segments are available from stock.

Ferodo M.Z. brake lining is an asbestos base solid weave metallic friction material, zinc alloy wire being introduced in the weaving operation. It is preferably supplied in segment form, shaped to definite dimensions as to length, width, thickness and radius. It can, however, be supplied in strip form for special applications. The coefficient of friction of Ferodo M.Z. lining for design purposes should be taken as 0·3. This material is intended to meet the requirement of a heavy duty brake lining having a constant medium coefficient of friction throughout its temperature range. It is suitable for running against all good quality cast-irons and cast alloy irons, and similar quality steels having a Brinell of 180 and over. Ferodo M.Z. lining is available from ¼ in. to 1 in. thick and in widths up to 18 ins.

Ferodo VG.91 is a rigid moulded material containing random asbestos yarn spun on brass wire. This friction lining has exceptionally high temperature resisting qualities and will function satisfactorily up to 1,000° F., providing the mating surface will withstand this very high level. Ferodo VG.91 has a moderate but slightly rising friction value with temperature, the cold μ for design purposes being taken at 0·25. This friction lining is an extremely rigid product, and must therefore be manufactured to its final dimensions with respect to length, radius, width and thickness. Preferably it should be used only against high quality cast or alloy irons, or if it is imperative to employ steel, the latter should have a Brinell value of not less than 200.

Ferodo M.R. friction lining is a solid weave, non-metallic, asbestos base material. In its normal form it is a hard, rigid brake lining and definite dimensions as to length, width, thickness and radius should be specified when ordering. In special circumstances this material can be supplied in flexible lengths to be fitted to band brakes, etc. Ferodo M.R. lining has a higher coefficient of friction than other asbestos materials, and for design purposes this value can be taken as 0·35. It is available in standard ranges of thicknesses from ⅛ in. to ⅝ in. and in widths up to 18 ins. It is suitable for use against all good quality close-grained cast and alloy cast-irons, and against similar quality steels of 150 and over Brinell. In common with all non-metallic

friction linings, Ferodo M.R. lining requires that the initial finish of the mating metal surface should be as good as possible; this is best attained by grinding.

The brake lining thicknesses given represent standard sizes, but materials beyond these dimensions are available for certain applications.

'Ferodo' Clutch Linings.

Cone Clutches.—Ferodo Fibre and Ferodo Bonded Asbestos linings are both available in cone form, the material being radially woven facilitating formation into cone linings and ensuring uniform density across the face of each lining. For clutch design purposes the coefficient of friction of Ferodo Fibre should be taken as 0·48 and that of Ferodo Bonded Asbestos as 0·28. The minimum included angle for Ferodo Fibre should be 36° and for Ferodo Bonded Asbestos 24°. Ferodo Fibre should not be adopted where the maximum operating temperature is likely to exceed 220° F.

Plate Clutches.—Ferodo Fibre linings are not suitable for fitting to plate clutches, as the temperature of the plates is generally above the safe maximum for this class of material. Several types of asbestos base linings are available in disc form for plate clutches, their construction differing according to their dimensions and the duty and conditions under which they are to operate.

Ferodo R.A.D.11 facings are manufactured from solid, radially woven, metallic (brass wire) asbestos, and are available in a large range of diameters, bores and thicknesses. There is no visible joint in these facings, this joint being cemented during manufacture, which obviates the weakness and other disadvantages of the more usual wire stitched butt joint. When dimensional requirements, particularly wide face widths, preclude the above facing construction, similar material is available in cut out form up to 21 ins. outer diameter. Beyond this dimension, each facing is supplied in four or more equal segments which are riveted to the metal carrier plate to form a continuous disc. These clutch facings should be run dry (unlubricated) and for design purposes the coefficient of friction should be taken as 0·28.

Ferodo R.A.D.5 facings are similar to Ferodo R.A.D.11 discs with respect to material and construction and are intended for use in oil immersed clutches. The coefficient of friction of these facings for design purposes when running in oil should be taken as 0·1.

Ferodo L.M. facings are manufactured from a metallic asbestos base, rigid moulded material which can be run dry or lubricated. The coefficient of friction dry should be taken as 0·22 and lubricated as 0·06. This material can be supplied in one piece discs up to 36 ins. diam., any bore and up to 1 in. thick. Being a rigid, moulded material, gear teeth or splines can be cut in the periphery, when it will function satisfactorily as both friction facing and clutch plate.

'Ferobestos' Products.

Ferobestos products are manufactured by Ferodo Limited for a very large range of applications which have little or no connection with the brake and clutch lining field. They are made from a rigid moulded material having an asbestos base and given the availability of suitable moulding tools, are produced in a variety of forms and sizes. Large quantities of non-metallic bushes are made in this material which has a relatively low dry friction, and therefore is particularly suitable for oscillating and sliding motions at comparatively slow speeds. This material is also completely resistant to the solvent action of any normal lubricant, including water, and a large range of chemicals and is therefore particularly valuable as a bearing material where it is completely submerged in a liquid which will attack orthodox bushes. There is a large range of Ferobestos materials, each type having its own particular outstanding qualities such as chemical or temperature resistance, high structural strength, low friction, etc., etc., and it is suggested that the makers should be approached for particulars of these new products wherever it is thought they may be usefully employed.

SECTION XXI

PART III

Wire Ropes.

Whitecross 'Contra-Lock' Non-Rotating Ropes.

(*The Whitecross Co. Ltd., Warrington.*)

With the considerable advance made in recent years in the production of mechanical handling plant, there has arisen an increasing demand for steel wire ropes which possess no tendency to rotate under varying loads.

Such ropes must necessarily be constructed of multiple layers of strands so balanced as to counteract the tendency to tighten or slacken on the core as the load is imposed or released with consequential rotational movement. Many such designs have been evolved, but most ropes of this type were liable to become distorted in service owing to uneven rate of wear on the various parts, which had the effect of upsetting the exact torsional balance essential to a strictly non-rotating rope.

To obviate these difficulties, the Whitecross Co. developed the 'Contra-Lock' Patent Construction which by imparting a self-tightening action to the rope automatically takes up the wear on the respective parts of the rope and thus maintains correct balance throughout the life of the rope.

Sections of standard non-rotating ropes to which the 'Contra-Lock' Patent principle has been applied with success are shown below.

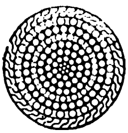

FIG. 1.

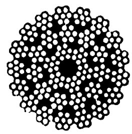

FIG. 2.

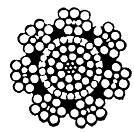

FIG. 3.

Fig. 1. 'Contra-Lock' Locked Coil Rope for high speed colliery winding.

Fig. 2. 'Contra-Lock' Multi-Strand Non-Rotating Rope for large balance ropes, sinking ropes and large crane ropes.

Fig. 3. 'Contra-Lock' Multi-Strand Non-Rotating Rope for light cranes and hoisting appliances.

In addition to the above, several special designs have been evolved incorporating the same principles, but adapted to meet unusually arduous or difficult conditions which the standard ropes proved unable to withstand. Included in these special deisgns is the Whitecross Co. Ltd.'s Koepe Winding Rope, which is in use at many of the largest collieries in Belgium. Special provision is made in this construction to obviate slip on the Koepe pulley and to reduce elongation under load to a minimum.

For small standard round or flattened strand ropes required to work, as is so oftent he case, in mechanical handling plant, round pulleys of small diameter and subjected to several reverse bends, it has been found that the application of the Whitecross preformed process has effected a material improvement in the life of the ropes. In this process the wires are first of all formed to the exact helical pitch of the strand, each strand then being treated in the same way to give the desired pitch before closing into the finished rope. This process eliminates all tendency to liveliness so that the load is evenly distributed on the individual strands and bending stress is alleviated. Further, should any of the outer wires break owing to excessive wear, they remain in place and therefore minimise wear on the other wires and on sheaves, pulleys and drums.

SECTION XXI

PART IV

CHAIN DRIVES.

(Morse Chain Co., Ltd., Letchworth, Herts.)

The essential difference between the Morse inverted tooth rocker joint chain and other forms of inverted tooth chain is the joint construction of the former. Briefly, instead of the round pin in bushes or liners utilised in other constructions, the Morse joint consists of a two-part pintle so shaped that the one part rocks or rolls on the face of the other as the chain goes on or off the wheel teeth. The pin elements are so held in alternate links that sliding friction, either between link and pin or between the two pins, is eliminated, and hence a very high degree of mechanical efficiency is assured, while, as a further consequence, chains with this joint construction are not so dependent on lavish lubrication as are those comprising the old form of round pin with its sliding surfaces between pin and bush.

The latest form of a Morse rocker joint inverted tooth chain is illustrated in section, fig. 1; while fig. 2 shows the position of the respective pins in a driving link plate, and fig. 3 shows the pins in their position relative to each other. It will be noticed that the bearing surface extends

throughout the width of the chain. The pins for all practical purposes form an integral part of the link, and hence the only motion which takes place at the joint is a rocking movement. These chains are made to work with wheel teeth of a shape to permit of exceptionally quiet running, even at high speeds; the drives complete being furnished by the Morse Chain Company, Ltd., to specific requirements which should indicate the h.p. to be transmitted, the speed of driving and driven shafts in r.p.m., the distance between shaft centres and the type of load. The introduction of the Morse rocker joint construction has rendered available the benefits of the inverted tooth chain to large powers, and such drives up to 5,000 h.p. in one transmission have been

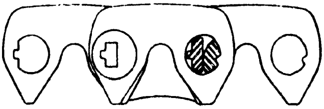

FIG. 1

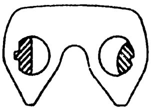

FIG. 2.

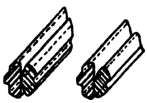

FIG. 3.

FIG. 1.—Rocker Joint Chain Section.
" 2.—Position of Pins in Link.
" 3.—Relative Position of Pins.

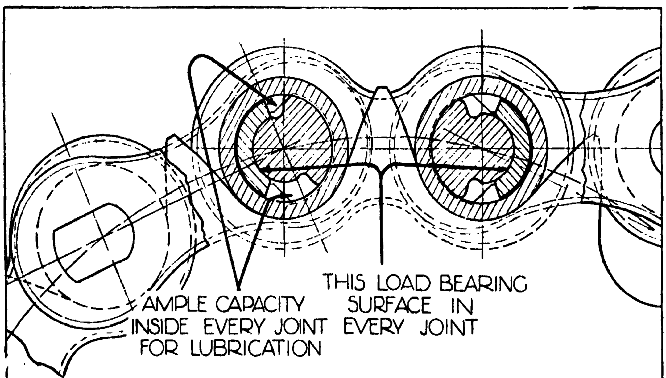

FIG. 4.—Morse Segmental Bush Roller Chain Section.

successfully furnished. These chains are manufactured up to 2-in. and 3-in. pitch to take care of such high power drives. The general applicability of a Morse Rocker joint chain is shown by the fact that it is made in numerous combinations of widths and pitches, the latter ranging from ⅜-in. to 3-in. pitch, suitable for rotary speeds ranging from 4,000 r.p.m. downward.

A further important feature in the field of power transmission by chains is the Morse patent roller chain. There are of course great varieties of power transmission for which, on account of

their slower speeds or the absence of demand for a high degree of quietness in running, the roller chain is eminently suitable. The distinguishing feature of the Morse roller chain again lies in the joint construction. As will be seen from fig. 4 the ordinary round bush has been eliminated and its place is taken by a segment secured to the inside links, while the pin is of such shape as to form a segmental portion, leaving a semi-circular portion to bear against the segmental bush. This pin is riveted into the outside links.

It will be seen from the above figure that the special features of this new roller-chain are as follows:—

1. *No Frictional Movement under Load, against Inside of Roller.*—As the roller and tooth engagement fixes the pin (or bushing) at that particular point, the bearing pressure is always taken on the *inside of the bush*, as the adjacent link with its pin (or bushing) flexes in engaging with the sprocket.

2. *Uniform Joint Action.*—In view of note 1, the frictional bearing surface is the same for every joint, *i.e.*, always between pin and bushing, consequently the rubbing velocity is proportionately less, owing to the smaller radius of contact.

In the conventional (round pin) roller chain, with the roller link fixed on sprocket, and the pin link about to engage, movement takes place between the *pin and bushing*; but with the pin link on sprocket and the roller link about to engage, movement takes place between *pin and bushing and bushing and roller*; consequently there is a different joint action during the engagement of each alternate link.

3. *Bearing Surface.*—In the round pin chain the bearing surface is virtually 'line contact' (owing to the necessary working clearance) whereas in the Segmental Bush Joint, a uniform arc of contact is secured, thereby reducing greatly initial 'bedding down' and chain elongation.

4. *Lubrication.*—In the case of the conventional round pin chain oil can only reach the pin via the small clearance between the pin links. In the case of the Morse Roller Chain, however, additional lubricant reaches the joint at the point of greatest clearance (between roller and link plate), and is at once in direct contact with the bearing surface. Moreover, the flow is greatly facilitated by the pumping action of the relative movement of pin and bushing sections.

The manufacture of both inverted tooth and roller chains, it will be appreciated, renders feasible the production of chain couplings consisting essentially of two sprockets, one on either of the shafts to be coupled, the sprockets themselves being connected by either an inverted tooth chain or a roller chain. Such couplings have outstanding advantages in that, while retaining a measure of flexibility, they offer exceptional ease of installation and entire dependability. The finished outer faces premit ready check for alignment, and wrapping the chain round the sprockets connects the coupling; disconnecting is equally simple, consisting merely in the removal of one of the chain pins, when the chain can be taken off. Fig. 5 shows the 50 h.p.

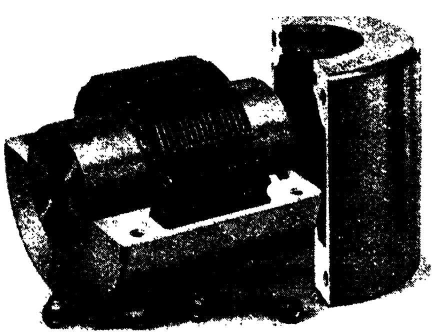

FIG. 5.—Morse Inverted Tooth Chain Coupling.

coupling at 1,440 r.p.m. Coupling sizes range from fractional h.p. to 1,000 h.p. or more, depending on the speed of shafts.

For protection, and to ensure lubrication, cases can be furnished totally to enclose the coupling, the case being filled with grease, thus assuring ample lubrication while excluding grit and dirt. Such a case is shown in fig. 5.

Renold Roller Chain.

(*The Renold and Coventry Chain Co., Ltd., Manchester.*)

The design of the Renold Roller Chain is based upon the use of simple cylindrical sections for the bearing pins, bushes and rollers: as a consequence it is possible not only to manufacture the parts themselves accurately, but the tools required for their production also lend themselves to a maximum degree of accuracy. For example, the holes in the plates are circular, and the bearing pins can be ground entirely on their working faces.

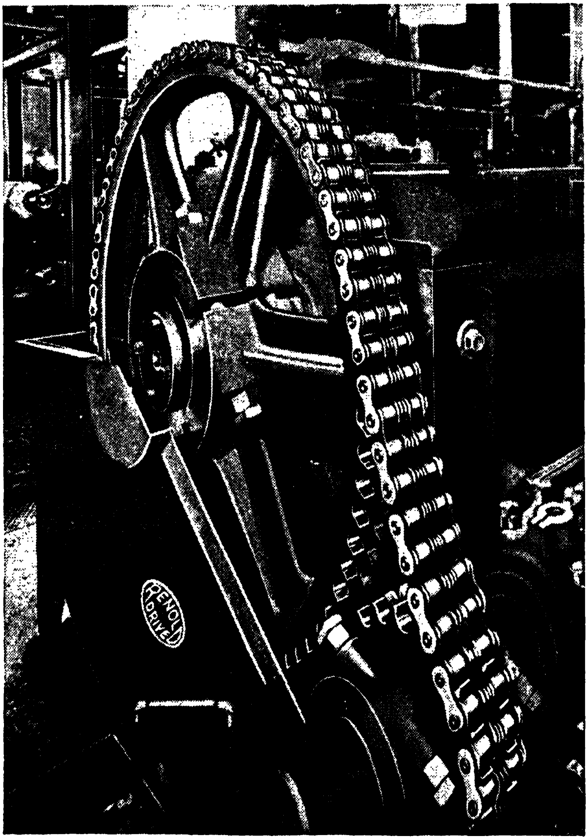

Fig. 1.—100 h.p. Renold Chain Drive 86·5 r.p.m. to 22·2 r.p.m. at Short Centres.

A major problem associated with the roller chain is how to obtain the necessary stability or fixation of the inner plates to the bushes, particularly in the case of the smaller pitches which

are required to run at very high speeds. Here again the advantage of the circular bush, which is the basis of the design, in allowing the necessary degree of force fit to be used to prevent lateral movement of the plates, will readily be appreciated.

Even so, the provision of the maximum amount of uninterrupted contact between the bush and the inner plate, which the circular bush achieves, requires to be supplemented by some positive method of attaching the plates if the chain is to operate successfully under ultra high-speed conditions. It was to deal with such conditions that the 'Mark 10' feature was introduced some

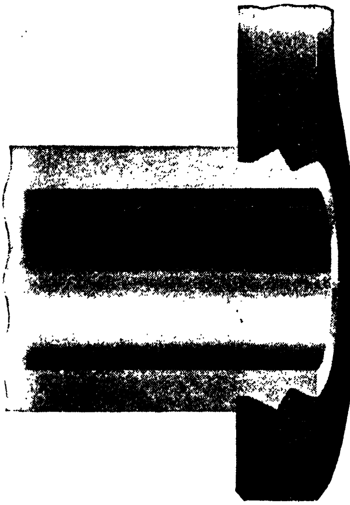

FIG. 2.—The keyed bush forced into the chain plate. The projecting keys prevent turning of the bush in the plate, and the metal filling the depressions prevents the plate being forced off endways.

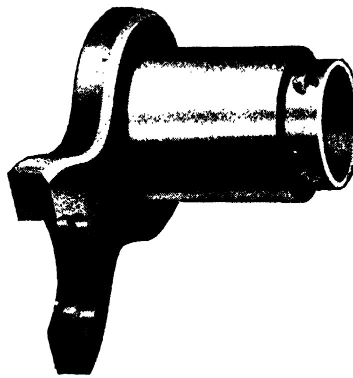

FIG. 3.—Keyed bush and plate, one end of plate cut away to show projections in the bore formed by the keys. These projections show the moulding of the metal by the keys.

few years ago. In the Renold 'Mark 10' chain the bushes are made with small keys pressed up on them and in the process of forming these keys small depressions are made in the surface of the bush in front of them. Hence, when the bushes are pressed into the plates, the metal removed by the keys is forced into the depressions in the bush and a compound lock is provided, making it impossible for the plates to be forced off.

The results of a series of tests of chain-drive efficiency carried out by the National Physical Laboratory show that the efficiency of a Renold chain drive, taken from stock, with no previous running, was 98½ per cent. The chain tested was a 1·0 in. pitch simple roller transmitting 25 h.p. from a shaft running at 900 r.p.m. on which a 23-tooth pinion was mounted to a shaft running at 363 r.p.m. carrying a 57-tooth wheel.

Before the advent of steel chains the choice between ropes, belts or gears was governed roughly by whether the deciding factors were positiveness, and perhaps compactness, in which case gears had to be used, or whether they were smoothness and elasticity, which pointed to the use of belts or ropes. The great achievement of the transmission chain is to combine to a remarkable extent these two sets of hitherto separated features. Chains are in fact as positive as gears, and as smooth running as belts and ropes, and have the highest maintained efficiency.

PART I

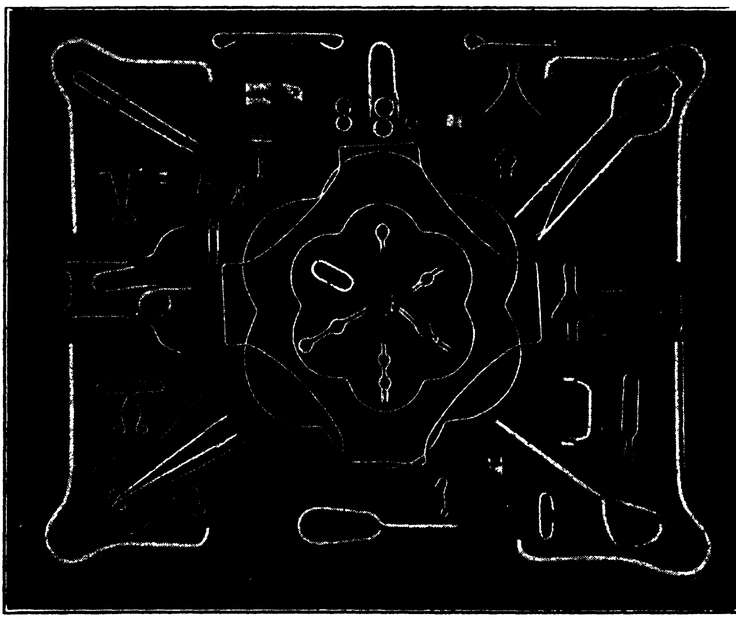
Machine Tools:

'HEENAN' AUTOMATIC MACHINES FOR THE WIRE AND STRIP INDUSTRY.

(Heenan and Froude Limited, Worcester, England.)

A number of machines are available for producing direct from the coil of wire or strip, a variety of components. These machines are :—

1. A four-slide Wire and Strip Forming machine (see illustration of various productions below).
2. A High-speed Nail Press.
3. A Chain Former, with separate Chain Welder.
4. A Ring Coiling machine, also capable of producing short coil springs.
5. A Hair Grip machine.
6. A Mattress Chain machine.



A small selection of the components which can be produced on 'Heenan' Wire and Strip Forming Machines.

The 'Heenan' Wire Forming and Strip Forming machines are designed on the basis of universal application and, when suitably tooled, can produce a very large variety of components direct from the coil of wire or strip. There is practically no metal industry which does not employ a variety of products which could profitably be produced on these automatic machines.

A large range of articles is at present being manufactured automatically on 'Heenan' machines, and the universal nature of these is such that one machine is capable of manufacturing automatically components which would normally require up to seven separate press operations.

In cases where production rates are such that a machine can be run for long periods uninterruptedly, the saving in production costs is frequently enormous, while where the consumption of one particular article can be catered for by running for a comparatively short period, the cost of installation is usually recouped very quickly by reduced production costs and floor space required, especially if sufficient different forms require to be made to keep the machine employed for a reasonable proportion of the year.

Each of the two types of machines is made in a range of sizes capable of producing components from 50 to 400 pieces per minute.

The working principles of the 'Heenan' Automatic Wire and Strip Forming machines are exceedingly simple and the tooling for different forms is fundamentally similar to that for ordinary power or hand presses ; each machine being a combination of several presses unified in a simple whole.

The 'Heenan' Automatic High-speed Nail Press produces headed nails from round or oval wire, the rate of output being very high.

The 'Heenan' Chain Former makes linked chain of the normal 'short-link' type, as used for cranes, etc., the operation being entirely automatic. The ends of the links are subsequently welded in the Chain Welder. Output is extremely high, the links being particularly well formed, and the welds of unusually good quality.

The 'Heenan' Ring Coiling machine produces rings with close-butted or overlapping ends, and by a simple attachment coil springs (compression or tension) can also be produced up to the maximum wire length which the machine will feed.

The 'Heenan' Automatic Hair Grip machine manufactures a standard form of grip, either plain or crimped, and with the ends sheared either square or rounded.

The 'Heenan' Automatic Mattress Chain makes the special form of chain used for spring mattresses, etc., and produces these in continuous linked-up lengths. A device is incorporated by which a link can be left unclosed at intervals, and the intervals themselves can be adjusted over a wide range.

'Rapidor' Sawing Equipment.

(Edward G. Herbert, Ltd., Manchester 19, England.)

'Rapidor' machines available in capacities from 6 ins. × 6 ins. to 12 ins. × 12 ins. are built for continuous high speed sawing. Using High Speed steel blades they will saw 28/30 tons tensile steel and brass at a cutting speed of 200 ft. per minute. Outstanding features are

Saw Frame is rigidly guided by two square slides placed diagonally for strength and to maintain alignment.

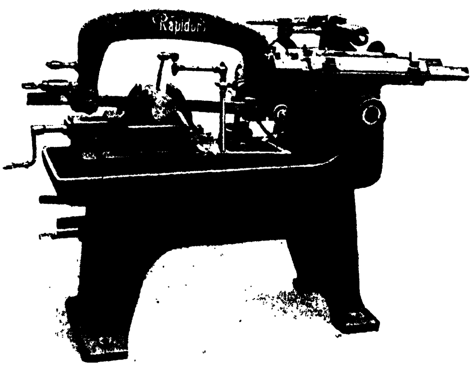
Saw Holders are rectangular, permanently in alignment and adjustable for different lengths of blades.

Tension.—The blade is quickly tensioned simply by turning a handle and a patented tension indicator shows when the blade is correctly strained.

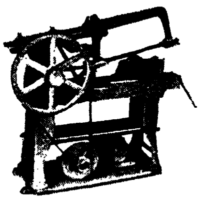
Pressure on the blade is regulated by a spring and a pressure indicator is fitted. Once the pressure is adjusted to suit the work being sawn no further alteration is required.

Starting.—A patent starting valve on the dashpot enables cuts to be started on a sharp corner without damage to the blade teeth.

Automatic Lift.—The saw blade is lifted automatically on the return stroke by means of a simple oil dashpot in conjunction with the angular setting of the saw.



'Rapidor No. 1 Sawing Machine.'
6″ × 6″ capacity arranged for single speed Belt Drive.



'Rapidor Manchester' Motor Driven Sawing Machine.

Length Gauge.—**An adjustable gauge is fitted on all 'Rapidor' machines.**

An adjustable automatic stop is incorporated to stop the machine at the finish of each cut.

Vice **is of the heavy screw type with roller thrust bearing on the screw. Loose jaw swivels to grip taper or irregular work and the whole vice can be adjusted on the T-slotted** table. Graduated swivel vice is supplied as an exrra.

Suds Pump **is of the gear type and has a positive roller chain drive. Iron piping with strong brass joints is provided for the suds.**

Lubrication.—**Grease gun lubrication ensures that all parts are perfectly lubricated.**

The' Rapidor Manchester' Sawing Machine **is a reliable and** inexpensive light **hacksawing machine, with a capacity of 6 ins. × 6 ins., and was introduced for use in small shops, maintenance and repair shops, etc., where sawing is not undertaken on a production basis. The essential and proved features of the heavier production 'Rapidor' machines—namely, double square steel slides, automatic relief on return stroke by oil dashpot, and the 'cutting on a corner' method of applying pressure—have been incorporated to ensure straight and trouble-free sawing.**

The firm is again manufacturing a full range of testing machines covering tension, compression, transverse, fatigue hardness and other tests; also static-dynamic balancing machines.

H.S.S. hacksaw blades, saw blade sharpening machines are also included in this firm's products.

SCREWING MACHINES (PRODUCTION).

(*Charles Winn & Co., Ltd., Granville Street, Birmingham,* 1.)

The illustration (fig. 1) shows the latest model heavy pattern high speed Tube and Bolt Screwing Machine, No. 4 size, the capacity being 1-in. to 4-in. tubes, and 1-in. to 4-in. Whitworth bolt

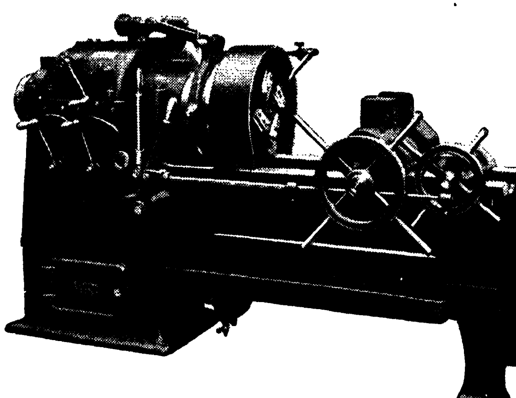


FIG. 1.

threads, and provided with tangential die head, with automatic opening and closing attachment also powerful open-jaw duplex-grip vice, with geared right- and left-hand vice screw, specially for gripping heavy work, and rack and pinion traverse with two machine-cut racks. A large oil tray and reservoir are fitted under the bed of the machine, with a self-priming rotary gear type oil pump at the back driven off the main driving shaft at constant speed.

The machine is fitted with single pulley drive and four-speed gearbox with forward and reverse movements, so that right-hand and left-hand threads can be cut with equal facility, or alternatively the machine can be provided with eight speeds for right-hand screwing only, the gears

being in heat-treated steel and running in an oil bath. A multi-disc friction clutch is provided for stopping and starting the machine, with clutch lever shown at the front of the headstock.

This machine is also made fitted with 5 h.p. four-speed A.C. motor and provided with two-speed gear, giving a total of eight spindle speeds. A reversing switch can be fitted to enable the eight spindle speeds to be used for either right-hand or left-hand screwing.

An interesting feature is the patent thread length indicator, fitted to the saddle, giving a clear visual indication of the length of thread being cut. This can be used independently or in conjunction with the automatic opening and closing diehead attachment.

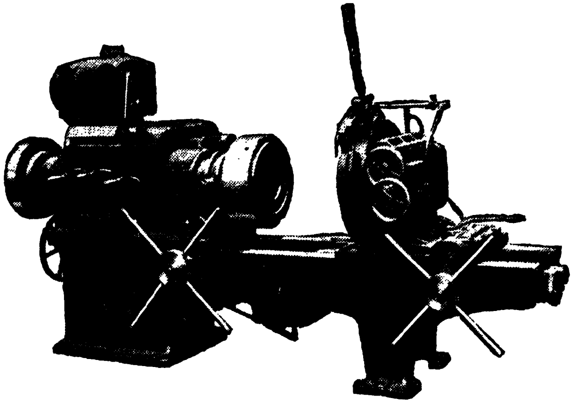

FIG. 2.

Fig. 2 shows an electrically driven high speed combined Screwing and Cutting-off Machine, No. 6 size, for tube works requirements having Winn's patent quick-grip self-centring chuck and hollow spindle for gripping and releasing the tube without stopping the machine. The chuck is operated by means of a geared capstan lever at the front. A self-centring steady chuck is fitted at the rear end of the spindle. The headstock is fitted with the latest type eight-speed change gearbox, with heat-treated gears running in an oil bath, and the multi-disc friction clutch with the operating lever at the front is provided for stopping and starting independently of the motor, which is 5 h.p. and is mounted over the gearbox.

The bed is fitted with a large oil reservoir and a rotary gear type oil pump is provided for lubrication to the screwing and cutting-off tools.

The machine is also provided with a leading screw, and the necessary change wheels with an operating lever on the saddle complete with gunmetal split nut, the saddle carrying a stationary die head of the tangential type, with an efficient cutting-off slide at the back, and has a capacity of 2½-in. to 6-in. bore tubes, although extra equipment can be provided if necessary for increasing the capacity from 1 in. to 6 ins. An electrically driven oil pump can be fitted in place of Rotary pump.

Patent thread length indicator, fitted to the saddle, giving clear visual indication of the length of thread being cut.

This machine is also made fitted with four-speed A.C. motor instead of gearbox.

The No. 2 size, high speed combined screwing and cutting-off machine shown in fig. 3 is driven by a four-speed A.C. motor and fitted with an air operated, double acting friction clutch, giving the machine two ranges of four speeds. One set of speeds is arranged for screwing and the other range, at increased speed, for cutting off and frazing.

The forged steel spindle, running in Timken taper roller bearings, is fitted with Winn's patent quick-grip self-centring chuck which is operated by means of a capstan lever at the front. The rear end of the spindle is fitted with a steady bush and ring steadies bored to suit tube sizes.

The saddle carries a stationary tangential diehead with a cutting off and frazing arrangement at the back. The safdle is moved by means of machine cut rack and pinion and is arranged to operate the double acting clutch.

An electrically driven oil pump is fitted to supply lubricant for screwing and cutting off.

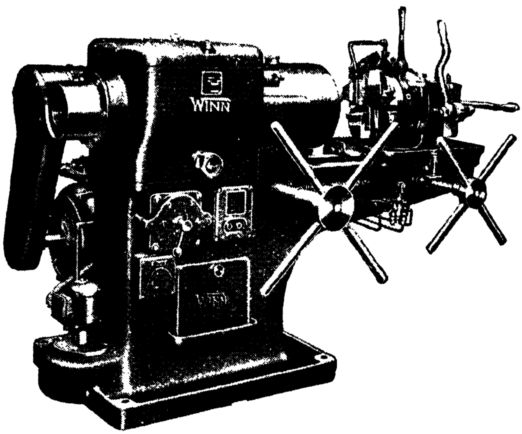

Fig. 3.

SCREWING MACHINES (GENERAL PURPOSE).

Charles Winn & Co., Ltd., Granville Street, Birmingham, 1.)

The illustration (fig. 4) shows a No. 3 size, fig. 6197–BE, machine for screwing up to 3-in. bore tubes and 2-in. bolts.

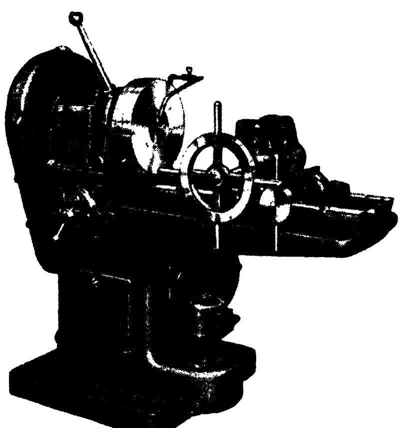

FIG. 4.

This machine is directly driven by an A.C. four-speed motor and has a built-in change-pole controller.

The motor is mounted on slide rails at the back of the machine so that the chain tension can be maintained. A split bearing is provided for the headstock and radial dies are used. The diehead is of the type opened by a bow lever, operating through gun metal slippers and a sliding head.

An interesting feature is the patent thread-length indicator which gives visual indication of the length of the thread being cut, thus enabling the operator to release the dies immediately the required length has been screwed.

The machine is of robust and compact design, and although primarily intended for maintenance and repair work, can be used for production work where a full-production machine is not warranted, but where there is considerable continuous repetition work.

Adjusting strips are fitted for taking-up wear on the saddle and vice. An independent constant-speed motor-driven pump provides an ample flow of cutting lubricant to the work. When required, a cutting-off plate can be fitted to the machine. Necessary chuck, nut holders, and taps for tapping can be supplied with this machine when required.

Other sizes made are No. 1, No. 2 and No. 4, all fitted with electrically driven oil pumps.

This type of machine, when fitted with tangential diehead and automatic opening and closing attachment, becomes a full production machine, and these features can be embodied upon request.

TUBE CUTTING-OFF MACHINES.

(Charles Winn & Co., Ltd., Granville Street, Birmingham, 1.)

The illustration (fig. 5) represents the latest model high speed cutting-off machine for modern tube works requirements, being fitted with Winn's patent Quick Grip self-centring four-jaw chuck

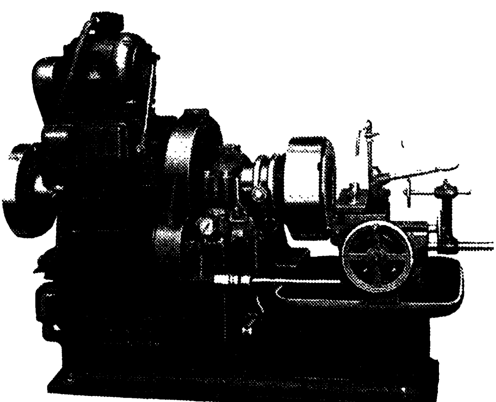

FIG. 5.

operated by a pneumatic cylinder, complete with control valve mounted on front of machine and a three-jaw self-centring steady chuck at the back end of the hollow spindle.

The cutting-off slide has power feed and frazing attachment. The machine is driven by an A.C. four-speed motor. The driving shaft is fitted with a multi-disc clutch operated by a lever in front of the machine.

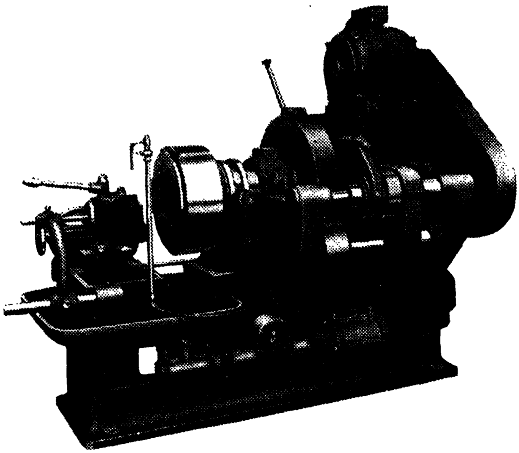

FIG. 6.

The illustrations (figs. 5 and 6) show a No. 6 size machine, suitable for tubes 1-in. to 6-in. bore Other sizes made are No. 2, No. 4, No. 8 and No. 12.

SECTION XXII

PART III

Steam and Power Hammers.

Drop Hammers.

(Brett's Patent Lifter Co., Ltd., Coventry.)

The modern drop hammer provides for extreme rigidity and strength of guiding effect of the tup. Accurate and permanent adjustment is a vital necessity in the use of multiple impression dies, which has superseded the old method of separate dummying. The side shock created by one sided impressions has to be resisted by guide rods capable of withstanding heavy stresses in all directions.

The Automatic Board Drop Hammer possesses the merit of a perfectly free fall. Operating with multiple impression dies, the blows of the hammer are so synchronised that they provide just the time necessary to move the bar from one impression to another. It can be said that the board hammer works at the maximum drop hammer speed. There is no class of drop forging appliance capable of greater production.

Clipping Presses are essential for all drop forging work. They should be of solid construction and capable of withstanding heavy overloads without risk. In some cases it is preferable to use the three-start clutch which gives almost instantaneous application of the slide to the work.

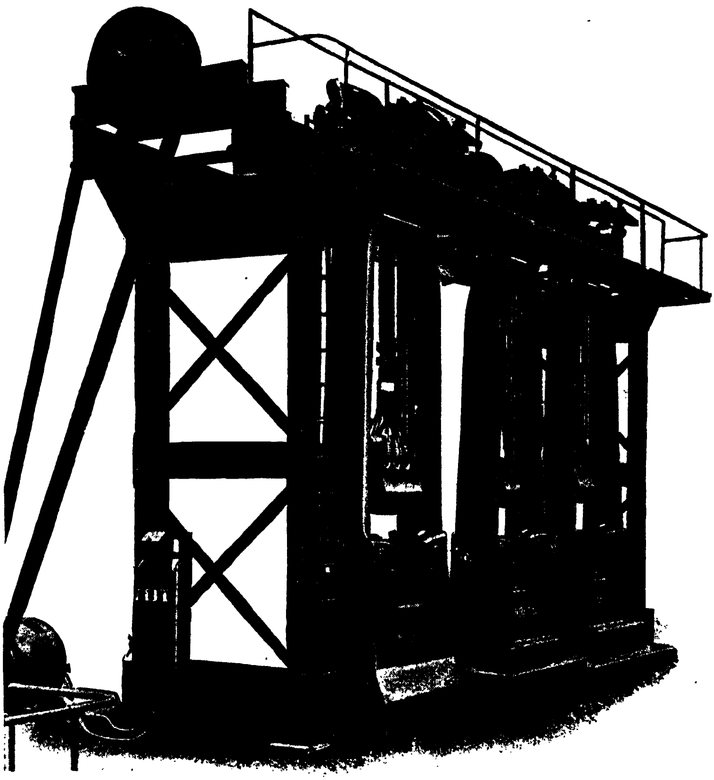

Fig. 1.

FIG. 2.

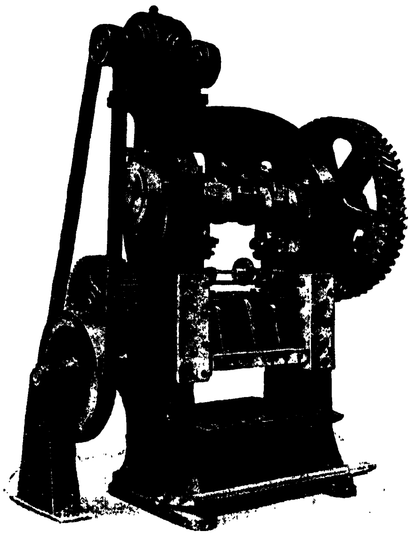

FIG. 4.

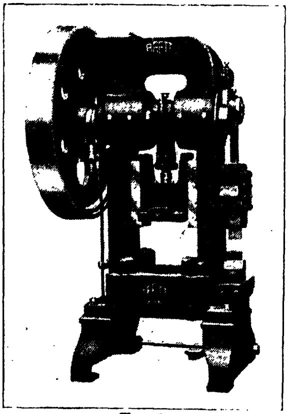

FIG. 3.

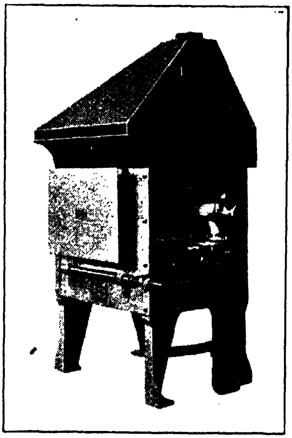

FIG. 5.

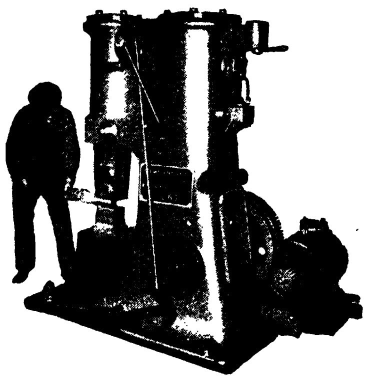
In a general way clipping presses for drop forging are ungeared. Clipping the stamping is a momentary operation and the heavy flywheel stores up sufficient energy to actually do the work, with the advantage that the job is perfectly clean. For very large stampings, such as 4 and 6 throw cranks for motor cars, front axles, etc., gearing is necessary. Fig. 4 shows a typical press constructed for the purpose. It is a very powerful machine and is in consequence capable of dealing with very heavy work.

Oil Fired Furnaces possess many advantages. They give a very intense heat with very little sulphur. Bars are heated quickly and uniformly. There are many types of burners but the one shown is constructed on special lines and provides for combustion chamber, pre-heating of the air supply, positive atomisation and perfect control. The design of furnace shown is suitable for bar heating. Where separate sections are used, naturally these must be placed on the floor of the furnace for which a different design is necessary, but the same burner is utilised.

PNEUMATIC POWER HAMMERS.

(*Alldays & Onions Ltd., Great Western Works, Birmingham.*)

These hammers, which are designed for either belt or motor drive, are made in six sizes, ½ cwt., 1 cwt., 2 cwt., 3 cwt., 5 cwt. and 7 cwt., having strokes of 8", 12", 14", 18", 21" and 24" respectively. As may be seen from the accompanying illustration their design is particularly simple, comprising a hammer and an air pump combined into a single unit.



Pneumatic Power Hammer.

The body of the machine, consisting of the hammer and air pump cylinders, crank case and the foot, through which the anvil body passes, comprises a single rigid casting. The upper part of the hammer or tup forms a piston which reciprocates in the hammer cylinder. An adjustable guide bar prevents the tup from turning and the height of forging is automatically set to any distance within the range of the machine. The air pump consists of a piston with a large bearing surface reciprocating within a cylinder which communicates with the upper part of the hammer cylinder through a port at the top. Interposed in the air port between the two cylinders is a rotary valve which controls the air supply to the hammer cylinder and all movements of the tup. The setting of this control valve is done by means of either a hand lever or foot treadle gear and it may be arranged for the hammer to be held up or down or for the striking of continuous heavy, medium or light blows. When the valve is set for the holding up position, air is drawn from the hammer cylinder on the downward stroke of the pump piston and the tup rises to the top of its stroke by virtue of the vacuum formed above it and the atmospheric pressure on its under surface. On the following compression stroke the piston expels the air in its cylinder into the atmosphere and, with this setting, so long as the piston reciprocates, it continues to exhaust air from the hammer cylinder. When set for holding down, in order that a workpiece may be gripped between the tup and the anvil, the valve allows the air from the pump to be continually fed into the hammer cylinder where it is compressed and builds up a load on the upper surface of the hammer. The valve can also be set for the tup to give full, or heavy, blows or light blows. When giving heavy blows the valve setting permits a free passage for air between the pump and hammer cylinders and as the pump piston reciprocates the tup also moves up and down striking its heaviest blows. In order to strike light blows the air from the pump cylinder is partly exhausted and striking of the tup is proportionally light. Single blows are obtained without any special fitments or gear. The mechanism of the valve is such that when the control levers are released, the tup returns to its highest and inoperative position and remains there so long as the pump crankshaft revolves.

SECTION XXIII

PART I

Metallurgy.

Non-Ferrous Alloys.

DURALUMIN

(Registered Trade-mark.)

(James Booth & Co., Ltd., Nechells, Birmingham.)

'Duralumin' is a registered trade-mark applicable to a group of important engineering alloys whose mechanical properties are capable of wide variation by suitable heat treatment. The alloys contain 90 to 98 per cent. of aluminium, the remainder being made up of copper, manganese, magnesium, silicon, iron, zinc, etc., according to the type of alloy.

'Duralumin' was introduced by James Booth & Company in about 1912, and was thereafter developed and improved steadily. Much of its development was carried out in conjunction with the aircraft industry, which was quick to take advantage of the low density and the high strength/weight ratio of the new material. This phase is reflected in the existence of numerous Air Ministry DTD and British Standards Aircraft Specifications for this class of alloy such as the well-known BSS. 6L1 and 5L3, and DTD. 390. In recent years, however, the advantages of using aluminium alloys have been appreciated in many other spheres of engineering, and nowadays the greatly increased availability and reduced price of these alloys, have enabled them to take their place as second only to ferrous materials in general engineering importance. A comprehensive series of B.S.I. Specifications are available for this class of product and a new series will shortly be published.

There are now four main types of 'Duralumin,' all of which respond to heat treatment:—

'Duralumin "B"' is the modern form of the original 'Duralumin,' and it has been in wide use for many years. It is essentially an alloy of aluminium with copper, manganese and magnesium. The heat treatment given to this allow consists of a solution treatment at about 495°C. to take the copper and magnesium into solid solution followed by a rapid quench which retains this condition for a limited period at room temperature. For an hour or so after quenching the alloy is quite soft, but precipitation of submicroscopic particles causes a hardening, rapid at first but becoming slower with time; from a strength of 17 tons per sq. in. as quenched, the alloy reaches 25 to 28 tons per sq. in. in five days and retains this strength indefinitely.

The soft condition immediately after quenching provides a very convenient opportunity for carrying out a moderate amount of forming, the subsequent aging then taking place without distortion. For more drastic deformation the material is annealed at 380° C., which treatment agglomerates in precipitate, thereby removing its hardening effect and produces the softest condition of the alloy. As with most other metals, difficult forming may be done in stages with inter-stage annealing, with the usual proviso that the amount of work at each stage should be above about 5 to 10 per cent., or coarse grain may be produced at the next anneal. For full mechanical properties, of course, the material must finally be solution treated and quenched to allow of age hardening.

'Duralumin "S"' is a more recent development of 'Duralumin "B"' and it is characterised by a higher silicon content. As solution treated and aged at room temperature its properties are very similar to those of 'Duralumin "B,"' but if it is given further 'precipitation' heat treatment at about 180° C., it undergoes a second precipitation which affects particularly the 0·1 per cent. proof stress of the material. The more refined methods of design, based largely on

proof stress, thus allow a higher working stress in 'Duralumin "S,"' by virtue of its relatively high proof stress. This alloy was widely used during the last war in such highly important aircraft members as wing spars, and its use as high strength sheet is steadily increasing. Solution treatment is carried out at 505° C. and requires somewhat more critical control than 'Duralumin 'B."'

'Duralumin "Q"' is a higher strength grade of 'Duralumin "B,"' and is mainly used in the form of clad sheet and tube. This alloy has a solution treatment temperature of 495° C.

The second type of 'Duralumin' is typified by :—

'Duralumin "H"' which is essentially an alloy of aluminium, manganese, magnesium and silicon. It is fully heat treatable, but in the annealed state it is very readily workable and may be spun and pressed into the deep pressings with ease. Solution treatment produces a moderate strength alloy with good ductility and excellent corrosion resistance. It is not susceptible to natural ageing. If the solution treated alloy is precipitated at about 200° C., its strength is very greatly improved, and in this condition it gives a very high ratio of proof stress to ultimate stress. With this alloy considerable forming may be done after quenching without any time limit being imposed by age hardening, as in the case of 'Duralumin "B"' or 'Duralumin "S,"' and of course, it may be subsequently fully hardened by precipitation heat treatment. A variant of this alloy is 'Duralumin "E"' which consists of a 'Duralumin "H"' type alloy to which copper has been added for increased strength. The behaviour of this alloy in its heat treatment lies between that of 'Duralumin "H"' and 'Duralumin "B."'

The third type of 'Duralumin' is the newly developed :—

'Duralumin "K"' which contains zinc and is the strongest aluminium alloy yet produced. It is intended for use in applications requiring particularly high strength with the high proof stress/ultimate stress ratio given by precipitation at about 135° C. Solution treatment of this alloy is conducted at 460° C., followed by quenching in water. The aircraft industry is steadily exploring the possibilities of this alloy and considerable experience is being gained in its manufacture and fabrication. A somewhat softer alloy of this series is 'Duralumin "L,"' which contains a lower proportion of hardening elements, and is used for the manufacture of sheet and tube.

The fouth group of 'Duralumin' is :—

'Duralumin "T"' and 'Duralumin "J"' which are intended for specialised service at elevated temperatures and possess good creep strength at temperatures up to 250° C.

Other Aluminium Alloys.

In addition to the 'Duralumin' range of alloys there is an interesting series of alloys of aluminium and magnesium which are not heat treatable but which have interesting properties in the annealed condition, and whose strength can be increased by cold working. These alloys which are sold under the registered trade names of 'MG2,' 'MG5' and 'MG7' contain 2, 5 and 7 per cent. of magnesium respectively. These alloys give an interesting combination of workablity and strength, they are weldable and have a high resistance to corrosion. In addition, they possess the peculiar property of steel in that they have a fatiguel imit. In general the heat treatable alloys do not have such a limit.

Aluminium alloys possess good resistance to corrosion, in general far better than structural steels. In most applications to structures when frequent inspection is not practicable, paint coatings are naturally applied. For the best possible protection an undercoat containing zinc chromate is applied to a surface specially prepared for adhesion by anodising or by a simple chemical dip. Almost any kind of paint can then be put on top of the undercoat.

Sheet material, particularly for aircraft use, is often used in very thin gauges, and corrosion cannot be tolerated, nor can heavy paint coating. In these cases, sheets are used in which a strong alloy core has an integrally bonded pure aluminium coating rolled on during manufacture. This gives the composite sheet a very high reistance to attack, and as is well known, the stressed skin of modern aeroplanes is of such material quite unpainted. Clad sheets of this description are sold under the registered trade name of 'Aldural.'

Actual structures have demonstrated that aluminium alloys may be attached to steel without detriment, provided an ordinary paint cover is applied. Contact with most other non-ferrous metals, however, sets up an electrolytic action and has to be avoided particularly in the case of copper and brass.

Practically all the alloys described above may be welded, but in general the heat treatable alloys containing copper are difficult to weld and when welded the properties of the welded joints are not attractive. ' Duralumin " H " ' welds very well, but the highest properties in the welded joints are given in the case of the aluminium magnesium alloys. Some specialised experience is desirable in order to produce the best type of welds in these alloys, but the strength of such joints is upwards of 90 per cent. of the strength of the parent annealed metal. The alloys may also be jointed by soldering and if the correct types of solders are used resistance to corrosion may be obtained, but users are not advised to embark on operations involving soldering of aluminium alloys without expert advice.

MACHINING.

The machining of the various ' Duralumin ' alloys does not present any great difficulty, they may be machined at considerably higher speeds than many other so-called free machining alloys, and normally they take a fine finish. In the softer conditions, however, and in the case of the 'MG2' and 'MG5' alloys, machining will not be so easy. It will generally be found that tools for cutting aluminium alloys should have more top and side rake than those which are used for free cutting brass or steel, and it is advisable to keep very keen edges on the tool with fine emery wheels, and care should be taken to keep the edges of the tools free from metal which may adhere to them by fairly frequent stoning.

Roughing cuts may be made dry, but with finishing cuts cutting compound is necessary. Suitable compounds are soluble cutting oil and mixtures of paraffin and lard oil in about equal proportions, will also be found to be suitable. If parts during rough machining are found to heat up, they should be cooled before the final finishing to size, as the co-efficient of expansion of ' Duralumin ' is higher than that of brass or steel, and some slight inaccuracies in dimensions may be noticed after cooling if this precaution is not taken.

USES OF ALUMINIUM ALLOYS.

A few of the uses which these alloys have found may be indicated. It will be appreciated that in all kinds of mobile units these alloys have great value because of their high strength/weight ratio. The value of light alloys in modern military aircraft has been much appreciated in recent days and, of course, it is in aircraft that much light alloy has been used in the past. In these post-war days, however, the strong light alloys are finding considerably extended applications in general engineering, and the British Standards Institution have embarked on the production of a series of general engineering specifications for all these alloys. It is hoped that these specifications will be published in the near future. Light alloys are used extensively in modern omnibus body manufacture, roofs, floors, window-frames, seats, baggage racks, heating and electrical equipment, treat plates, rails, handles, panelling and stressed parts of the chassis are made from these alloys. A further interesting use of the alloys has been the manufacture of mine skips. While at the present time considerable attention is being directed towards the use of certain selected alloys for marine purposes, the Admiralty have recently issued a booklet making recommendations in this connection. The tables below record the physical properties of the ' Duralumin ' alloys and a list is given of the specifications for all the alloys manufactured by the company. These specifications were issued by the Superintendent for the Technical Applications of Metals, under the heading S.T.A.M., during the war for use by the services. Relevant aircraft and B.S.I. specifications are also indicated in the table.

Specific Gravity	**2·6 to 2·9**
Co-efficient linear expansion	**24·0 × 10^{-6} per °C.**
Specific Heat	**0·214 (water = 1·0)**
Thermal Conductivity	**0·3 to 0·45 CGS units at 0°C.**
Electrical Resistivity	**3·3 to 5·3 Microhms per cc.**
Young's Modulus of Elasticity	**10 × 10^6 lb. per sq. in.**
Modulus of Torsion	**3·8 × 10^6 lb. " " "**
Poisson's ratio	**0·32**
Fatigue range	**10^7 cycles. ' Duralumin "B" ' ± 9·5 tons per sq. in.**

BULL'S METALS.

(Bull's Metal & Melloid Co. Ltd., Yoker, Glasgow, W. 4.)

Bull's Metals are strong, malleable alloys of good casting qualities, and equal to good gun-metal in resistance to corrosion. They are manufactured in two qualities, No. II and No. III.

Alloy No. II is suitable for founding purposes and extensively used for propellers and propeller blades, parts of guns and gun carriages, requiring the strength of cast steel with great toughness and resistance to corrosion.

Alloy No. III is very malleable and can be rolled, forged, stamped, or otherwise wrought at a red heat; this metal also casts well. Its composition ensures great resistance to corrosion and wear. It is absolutely non-magnetic.

Rolled in round, hexagon, angle, and section bars, or into sheets and plates; forged or stamped Bull's metal is used for pump rods, centrifugal pump spindles, rams, stern shafts, sluice valve spindles, parts of marine and hydraulic machinery generally. Forged propeller blades, propeller studs and nuts. Bolts, nuts, screws, studs, and nails. Parts of torpedoes and torpedo boats, ordnance, ammunition, etc. Condenser plates, strainer plates, doctor blades. Hull plates and angles for launches, torpedo boats, yachts, sailing and rowing boats.

The elastic and ultimate resistance to tensile, crushing, and torsional stresses are greater in the case of wrought Bull's metal than in mild steel, and higher working strains may therefore be used with Bull's metal. Where resistance to the action of water or chemicals enters as an important factor, Bull's metal, whether wrought or cast, becomes specially superior to steel.

'MELLOID.'

(Registered Trade Mark.)

This alloy is a malleable genuine bronze containing no inferior metal; its resistance to corrosion is very great. Its tensile strength in a rolled state when suitably finished is as high as that of mild steel; the strength is not appreciably affected at the temperature of high-pressure steam, whilst copper at such heat is very much reduced in strength and elasticity.

The alloy is perfectly malleable at *all* temperatures, from cold to blood-red heat; it has no brittle stage at a black heat like most metals and alloys, and at a red heat it is much superior in strength and toughness to mild steel under such conditions, and the alloy, under all conditions, is exceedingly tough.

'Melloid' meets the mechanical requirements referring to copper, naval brass, and rolled bronze specified by the Admiralty, the principal railway companies, and consulting engineers.

It is claimed that 'Melloid' will be found superior to all brass alloys, including naval brass yellow or Muntz metal, and also to wrought copper, wherever a combination of toughness, great strength, and a maximum resistance to corrosion is required.

'Melloid' is very suitable for condenser tubes and piston cooling tubes, boiler tubes, fire-box plates, boiling vats, beater bars, doctor blades, etc.

OIL COOLERS FOR HEAT TREATMENT OF STEEL.

(Heenan and Froude Limited, Worcester, England.)

The continuous introduction of hot steel into oil quenching tanks naturally heats up the oil, which retains heat for a long time, and rapidly becomes too hot to permit of the process being carried on.

Owing to the poor heat conductivity of oil, such arrangements as water-jacketing the tank or inserting pipe coils through which water is circulated are ineffective, the cool surfaces affecting only that portion of the oil with which they are in immediate contact, while allowing the main body to remain overheated.

The 'Heenan' system of oil cooling is to extract the hot oil by means of a suitable centrifugal pump and pass it through a 'Heenan' oil cooler before returning it to the quenching tank. This oil cooler is built on lines similar to those of the 'Heenan' water cooler described on page 1273. In effect, oil is distributed over a large cooling surface with which cool air is forced into contact. Circulating water is not used.

The use of this cooler is very widespread at home and abroad, and by its means the temperature of the quenching oil can be kept very much more uniform, thus promoting greater consistency in hardness of the heat-treated products.

SOLDERS AND SOLDERING FLUXES.

(Fry's Metal Foundries, Ltd., Tandem Works, Merton Abbey, S.W. 19.)

Soldering is a joining process for metals differentiated from welding by the fact that it is carried out at temperatures lower than the melting point of the joint members.

1. In soft soldering, lead-tin alloys melting at temperatures little above 183° C. are used. The value of the method lies largely in its simplicity and convenience. The strength of the joints obtained is not high, but soft soldering is often used for sealing joints made mechanically, *e.g.*, by lock seaming or riveting.

2. Hard solders, which are discussed later, give strong joints, but temperatures of 650°–1000° C. are required.

TIN-LEAD SOLDERS.

In soldering, adhesion of the solder to the joint members results from the wetting of the surfaces by the molten solder, which then alloys with, or 'tins,' the basis metal. For wetting to occur, clean molten solder must come into contact with clean basis metal; to ensure this contact a flux is used.

The main reasons for the use of the tin-lead alloys are their low melting point and the ease with which they 'tin' other metals. The melting point of the alloys varies with the composition. Pure tin melts at 232° C. (450° F.), pure lead at 327° C. (620° F.). In all alloys containing both metals, there is present a constituent known as the eutectic having the fixed composition of 63 per cent. tin, 37 per cent. lead. It melts at a temperature of 183° C. (361° F.), which is thus considerably lower than the melting point of either of the pure metals. Most solders contain a greater percentage of lead than the eutectic. Under the microscope, the excess lead in these alloys appears in the form of separate crystals distributed through the eutectic. The eutectic portion of the alloy melts at 183° C.; the lead crystals, however, melt only as the temperature increases beyond this, to some higher value. The alloy therefore melts not at one fixed temperature, but over a range of temperatures. The melting range increases with the proportion of excess lead present in the alloy.

Tinman's Solder, which is largely used for hand soldering, has a composition around 50 per cent. tin, 50 per cent. lead. This is sufficiently close to the eutectic to ensure that the proportion of lead crystals is small. As a result, the melting range is short and the alloy is completely molten at a temperature of approximately 210° C.

TABLE I.

* Lead balance. † Maximum.

The short melting range carries with it the very desirable advantages of ease and rapidity of melting and, conversely, of rapid solidification. Further, the alloy has excellent fluidity. These properties are of great value in bit and machine soldering. Fluidity is especially important in applications where the solder has to penetrate and flow into confined spaces, while ease of flow and speed of setting assist the production of smooth seams.

It is usual to add to solders a small proportion of antimony. This has two advantages. Firstly, the antimony increases the amount of eutectic in the alloy, being twice as effective as tin in this respect. Secondly, the solder is considerably strengthened, the improvement obtainable being as much as 20–25 per cent. The amount of antimony added must be carefully controlled during manufacture, however, or the solder will be sluggish and brittle.

For some purposes, *e.g.*, soldering of zinc, it is desirable to use a solder with a low antimony content.

The composition and properties of some B.S.S. solders are given in Table I.

Plumber's Solder.—As the lead content of the solder increases, the melting range increases. Thus an alloy containing 33⅓ per cent. of tin and 66⅔ per cent. of lead commences to melt at 183° C. and is fully liquid only when the temperature reaches 250° C. In the interval the solder is a mixture of solid and liquid metal; in this pasty condition it can be wiped around the joint.

All plumber's solders exhibit this characteristic feature. The composition varies slightly according to the type of work being carried out and the preference of the plumber. Decreasing the tin content increases the plastic range but gives a coarser 'wipe.' The following grades are widely used :—

Grade.	Melting Range.	Comments.
'Belfry'	185° C.–254° C. 365° F.–490° F.	Used for general plumbing work.
'Abbey'	185° C.–248° C. 365° F.–478° F.	Higher tin content, for best quality plumbing.
'Prior'	185° C.–245° C. 365° F.–473° F.	Extra rich grade for cable jointing.

Soldering Fluxes.

The soldering flux has two functions :—

(1) To clean the surfaces to be joined; (2) to protect them from the atmosphere during the soldering operation.

Fluxes can be divided into two main classes depending on the extent to which these two functions are fulfilled.

Active Fluxes are capable of effecting a considerable amount of cleaning. Killed spirits has been used in the past for general soldering work, but it is very corrosive and tends to leave a sticky residue in the joint itself.

Frysol active fluxes do not suffer from these disadvantages to the same extent. They are rapid in action and there are few metals which cannot be soldered by their use. They are generally employed for production work on iron, steel, tinplate, copper, brass and bronze, zinc, galvanised iron, nickel, etc. This flux is supplied in three forms :—

Frysol Soldering Paste Flux.
" " Fluid
" Tinning Salt.

All active fluxes exercise some corrosive action if they are left in contact with the members of the joint after soldering is completed. For many purposes this is not serious, as witness the fact that most of the proprietary fluxes marketed are of this type. It is desirable after soldering with these fluxes to wipe or wash the joint in order to remove any residue.

Safety fluxes are for use where cleaning of the joint after soldering is not possible and freedom from corrosion is essential. In general, these fluxes are slower and less effective in removing surface oxide; they act largely by protecting the metals from the atmosphere during soldering. As a result, it is necessary to start with clean surfaces. Their value lies in the fact that, having little chemical activity, they cannot cause corrosion of the joint.

Resin and tallow are in this class. They are suitable for soldering the less 'difficult' metals such as tin, pewter, lead and clean copper or brass. *Fry's Alcho-re* is a resin-base safety flux in the form of a liquid or paste, and is thus applied much more easily. It is especially suitable for electrical work, being non-conducting and completely non-corrosive. Further it sets rapidly after soldering, leaving a hard dry residue. This is important since most fluxes leave a sticky residue which absorbs moisture or traps dust or metal filings, thus lowering the insulation resistance of the joint.

Oleic Acid No. 9 and *Oleic Acid No. 10* are liquid safety fluxes intended for use mainly on tinplate. They are also suitable for soldering iron and steel if the surfaces are carefully cleaned before soldering.

Fryolux tinning compounds are mixtures of powdered solder and flux. They are thus convenient to use and, moreover, being very active, they give satisfactory results on metals that are normally only tinned with difficulty. The compound is simply sprinkled on the heated metal; if the latter is very dirty, rubbing with a scratchbrush assists the cleansing action of the flux. When a bright tinned surface has been obtained, surplus flux is wiped off.

Solder Paint and Solder Creams.

Solder paint and solder creams contain solder in powdered form intimately mixed with flux and provide a simple method of tinning or sweat soldering which for many purposes has superseded the use of solder in stick form or hot dip tinning.

They are best represented by *Fryolux* solder paint which carries finely powdered solder or pure tin in suspension in an active flux. The constituents do not separate and therefore stirring during use is unnecessary. The paint can be thinned down for some duties by the addition of small quantities of water and can be applied by a brush, pad, spraying or dipping. The residue left after soldering is non-greasy and can be removed by washing or wiping the joint.

Soldering by this method lends itself to mass production—the quality of the joints is less dependent on the skill of the individual operators. Many soldering operations can be mechanised, *e.g.* by passing the articles after applying the solder paint over a series of gas jets or through an oven or by the use of rotating jigs.

Soldering of Cast Iron.

Cast iron is difficult to tin owing to the presence of graphite and non-metallic inclusions. Pickling in hydrofluoric acid before tinning is sometimes recommended, but this method is dangerous and not always successful. For soldered joints, cleaning with an emery wheel may be sufficient, followed by soldering with an active flux.

For most purposes, including the tinning of bearing shells, it is advisable to use *Fryolux* tinning compound on account of its increased activity.

Soldering of Aluminium.

Soldered joints in aluminium can be made quite successfully, but their use is limited. The reason for this is that aluminium corrodes readily in moist conditions when it is in contact with other metals. Welding should therefore be used whenever possible to joint aluminium, using a filler rod of the same composition. Sometimes welding is out of the question owing to the high temperature required. Soldering is advantageous from this viewpoint, since there is much less danger of distortion or of softening the material. Soldering should not be employed for articles which are to contain water, and if the joint is likely to be exposed to moisture attack it should be protected by a coat of paint or enamel. If these precautions are observed, durable joints can be obtained.

In making the joints, a different technique is required for aluminium. The metal forms an oxide skin on the surface which is not removed by the ordinary soldering fluxes. The method employed is to remove it mechanically during the soldering operation. The solder is melted on the metal and used to exclude the air while the surface beneath is scraped with a sharp tool, such as a hacksaw blade or a scratchbrush. The aluminium can be tinned rapidly in this way if a solder of suitable composition is employed. The most satisfactory alloys contain tin, with zinc and other elements.

Fryal is an improved aluminium solder of this type. When molten, the solder is capable of penetrating the skin of oxide and therefore little scraping is required. Often it is sufficient merely to rub the alloy on the heated aluminium. Once a surface has been obtained in this way soldering can be completed with an ordinary lead tin solder. By this method, the aluminium need not be heated above a temperature of 250° C.

It will be observed that a flux is unnecessary.

Solders for Hot Dipping.

The hot dipping process is used either to provide a protective coating or as a means of soldering complicated assemblies, such as commutators or automobile radiators. The usual procedure is as follows:—

(1) *Degreasing*. If the article is greasy, treatment in an alkaline solution or in a trichlorethylene vat is necessary.

(2) *Pickling*. The surface must be free from oxide or scale. Pickle solutions containing sulphuric, hydrochloric or nitric acid are used, according to the metal being treated.

(3) *Fluxing*. After washing, the article is dipped in flux. Any of the liquid fluxes described above are suitable.

(4) *Dipping in molten solder*. The time of immersion should be no longer than that required to bring the article to the temperature of the bath. The latter depends on the alloy and the nature of the work being dipped, but the temperature should always be the lowest that gives a smooth coating.

(5) *After withdrawing the article*, the coating is allowed to set and is finally washed, dried and polished.

Soft Solders for Elevated Temperatures.

All tin-lead solders commence to melt at 183° C. (361° F.) but as they approach this temperature their strength falls rapidly. Thus the strength of a joint in brass made with Tinman's solder is reduced by 75 per cent. when the temperature reaches 150° C. (302° F.).

For soldered parts subjected to temperatures over that of the boiling point of water, it is advisable to use a special solder having superior resistance to elevated temperatures. The special solders listed in the table are much stronger than Tinman's solder, at temperatures over 100° C.

Solder.	Solder is completely Solid up to—
50/50 Tinman's solder	183° C. (362° F.)
H.T.3	236° C. (457° F.)
L.S.2	304° C. (579° F.)
L.S.T.1	308° C. (586° F.)
L.S.4	294° C. (561° F.)

H.T.3 is easy to apply, being free flowing, and can be used to replace tin-lead solders without any change being made in the soldering technique. It is suitable for electrical work since it has a high electrical conductivity and can be used with a safety flux.

Lead-silver solders have an even greater advantage in temperature resistance since they do not begin to melt until the temperature reaches about 300° C. (572° F.).

They need rather more experience and skill than normal solders as they do not possess the free running properties of the tin containing alloys. They should generally be used in conjunction with an active flux.

Amongst the applications in which the above solders are employed are aircraft cooling systems, hot water appliances and electrical machinery.

Fusible Solder.

Alloys with very low melting points are frequently used for special purposes. Among these may be mentioned solders for work which might be damaged by the temperature of application of tin-lead alloys; in safety devices, *e.g.* for operating alarms or breaking the electrical circuit when the temperature exceeds the melting point of the alloy; similarly, in fusible plugs for boilers; as fillers for the bending of thin walled tubes; and setting media for the mounting of punches and dies.

Table IV.

Fry's Alloy. No.	Alloy.	Melting Point. °C.	Melting Point. °F.
62	Tin-lead	183	362
20	Cadmium-bismuth	144	291
18	Tin-lead-cadmium	142	288
17	Tin-bismuth	138	281
15	Lead-bismuth	124	256
11	Tin-bismuth-cadmium	102	216
9	Tin-lead-bismuth	95	203
7	Lead-bismuth-cadmium	91·5	197
2	Tin-lead-bismuth-cadmium	70	158

Fry's Tube Bending Alloy, melting at 70° C., is used as a filler, providing the internal support necessary to prevent distortion in the bending of thin walled tubes. The alloy is melted in hot water and poured into the tube, which is plugged at one end. The filling is then chilled quickly by plunging the tube into cold water.

After bending, the tube is emptied by melting out the alloy in hot water.

Matrix Alloy is used for setting dies and punches in press tools. The punches are located in oversize holes in the backing plate and Matrix Alloy is poured into the clearance space. The alloy expands on solidification and so holds the part firmly in position. The alloy can be poured at about 230° C. so that the temper of the die is not affected.

HARD SOLDERS.

Hard solders were originally brasses containing a high proportion of zinc. More recently it has been found that the addition of silver to brass lowers the melting point of the solder and gives a better joint. Silver solders are now employed extensively despite their high cost.

BRAZING SOLDERS.

These usually contain about 50 per cent. of copper and 50 per cent. of zinc, and the melting point is in the region of 870° C., *i.e.* at a red heat. With this alloy it is possible to braze the commonly used brasses which have melting points of 900° C. or over, and, of course, higher melting point metals such as iron and steel.

The British Standard Specifications (No. 263—1931) cover three grades of brazing solder:

	Copper.	Zinc.
Grade AA	59–61	Balance
,, A	53–55	Balance
,, B	49–51	Balance

Grade AA is intended mainly for solder supplied in the form of wire or slittings.

With these solders, a borax type flux is generally used.

SILVER SOLDERS.

GRADE.	MELTING RANGE. Solidus.	Liquidus.	REMARKS.	SIZES.
B.S.S. Grade 'A' .	690° C. (1274° F.)	735° C. (1355° F.)	High grade silver solder especially suitable for electrical work.	$\frac{3}{16}$" × ·040" (normal stock size).
B.S.S. Grade 'B' .	700° C. (1292° F.)	775° C. (1427° F.)	Specified for general, aircraft and electrical engineering.	$\frac{1}{16}$" × ·040" 0·20 Sheet ·0625" Round.
F.E.F. . . .	595° C. (1103° F.)	630° C. (1166° F.)	Low melting point silver solder very fluid and easy to use.	Wire. No. 3 Silver Solder Flux
Standard . . .	740° C. (1364° F.)	780° C. (1436° F.)	An inexpensive, high strength alloy.	is suitable for these solders.

Of these alloys, F.E.F. quality is normally used owing to its low melting temperature. It should be used with No. 3 Silver Solder Flux, a powder which should be mixed with water into a smooth paste.

PRESSURE DIE CASTING.

(*Sparklets, Ltd., London, N.* 18.)

During recent years the business of pressure die casting has made very rapid strides both in the possibilities of economical production of intricate parts and in the development of alloys suitable for the purpose. The industry can, therefore, quite justly claim to be established on a firm basis for very great economies can be effected in the use of die castings as, following the manufacture of the tools or dies, the die-cast components are rapidly produced at a minimum of cost.

Economy is further assured by reason of the interchangeability of all die-cast parts produced from a given set of dies, and this is a constant factor since all dies are manufactured from a high grade steel suited to the requisite temperature for any particular alloy and, with accurate die-making in the first instance, mass production can be effected without alteration of form; whilst the elimination of machining operations owing to the fact that holes, slots, etc., are cast to finished dimensions in the actual die casting process is a fact far from negligible where costs are the major consideration.

Care must be exercised in the design of parts proposed for die casting, and avoidance of under-cuts on any internal form should receive consideration because, even if the production of the necessary dies is possible, such forms will generally operate against the most economic production.

Further, designs should incorporate as far as possible an equal thickness of section as this will facilitate the production of homogeneous castings. Where bosses, etc., are inevitable substantial fillets should be provided and, at the same time, advantage should be taken of the possibility of comparatively thin walls as a distinct saving of material is thereby effected. Sound advice from the specialist during the initial designing can have far reaching effect on the cost and utility of the ultimate product.

The development of die casting alloys has now made it possible to offer a product which can in many cases replace cast iron or brass, and with high grade zinc as the basic metal a tensile strength of 35,000 to 40,000 lb. per sq. in. is obtainable coupled with reasonable ductility. In addition to the above, the 'Sparklets' range of alloys includes many with aluminium, tin and lead as the basic metal—all of which can be successfully used to meet various requirements respecting weight or other service conditions.

Sparklets Woven Wire Braiding.

(*Sparklets, Ltd., London, N.* 18.)

Fifty years ago Sparklets, Ltd., introduced plaited wire in tubular form for the reinforcement and protection of rubber hose. At that time its application was limited to the armouring of rubber or rubber and asbestos tubing used principally for flexible gas and air connections. The technical developments which have taken place in all branches of engineering have resulted in a much wider application of this form of reinforcement and protection.

It has been proved by actual tests that where flexible hose has to withstand high gas or liquid pressure one coating of Sparklets Woven Wire Braiding, particularly if in the form of Multiplait, will increase the bursting strength of the tubing approximately ten times. By utilising a number of layers even greater strength can be obtained.

The great additional strength imparted to rubber or other hose by Sparklets Woven Wire Braiding is due to the method employed; the wires are closely woven and cover the surface of the tube entirely without affecting its flexibility. The wire coating will also prevent kinking of metallic tubing or flattening of rubber hose.

The high elastic limit of the wire used enables the hose to withstand sudden increases of pressure to a much greater extent than would be the case if it were more rigidly confined.

Sparklets, Ltd., pay particular attention to the corrosion-resisting qualities of the wire, especially in cases where steel wire is used.

It is not possible in the space of a short article to enumerate the multiple uses to which the plaited wire can be put, but the following will give some indication of its application: reinforcement and protection of hose for air or other gases, oil feeds, etc., ignition lead covering, casing for flexible metallic shafts, and protection for glass containers.

Special attention is drawn to the employment of wire braiding in the electrical industry, where it has been found to be a very efficient medium for armouring and screening of electrical cables, flexible electrical contacts, earthing strips for electrical apparatus, live rails, etc. For these purposes, the braiding can be obtained in tubular form or in flat strip.

SECTION XXIII

PART II

Welding and Cutting.

(*Barimar Ltd., 22/24 Peterborough Road, Fulham, London, S.W.* 6.)

Contrary to the hopes of a few years ago we have not reached a period when there has been any easement in the overload carried by so many factories and engineering works in this country. The export drive has necessarily increased this pressure and, at the same time, it has caused the withholding of a great deal of new equipment that is needed to supersede obsolescent machinery and other plant that is due for replacement on account of wear.

Sparklets
WOVEN
WIRE ARMOURING
& BRAIDING
THE WOVEN WIRES
PROTECT THE CABLE
FLAT-STRIP

In these circumstances little imagination is required to appreciate that serious situations are often threatened by the breakdown of some key machine unless the fault can be put right with complete dependability and a minimum loss of time. It is in this connection that Barimar scientific welding service has been applied with strikingly successful results.

A particularly anxious period was during the fuel crisis when the rapid repair of a wide variety of plant operated by electricity and gas undertakings called for skilful handling following upon failure through breakage, wear and corrosion. Sometimes it is impracticable to deal with these needs in the shops of the welding specialist as bulk or weight make transport impossible. In instances of this kind the welding repairs are done on the site and specially trained operators with self-contained equipment tackle the problem on the location. By this means too a great deal of time is saved.

The experience gained during the war years with emergency repairs, many of which had been regarded hitherto as beyond the bounds of practical accomplishment, has provided an invaluable background of knowledge that is being applied and extended at the present time.

Not all repair work completed by Barimar on the site is of the type associated with boilers, the massive castings of steel rolling mills, hydraulic presses and so on. In a recent instance a very large tractor broke down whilst at work, for the main casting, which is also the backbone of the chassis, fractured suddenly, fortunately there was reasonable accessibility and no subsequent machining was required. So the job was tackled and successfully completed on the spot where the breakage happened. It was during a period of extremely cold weather and screens of sacking had to be erected as a protection from the wind. Results, however, fully justified the trouble taken and no further weakness has been experienced.

A vital branch of industry in which a great deal of outstanding welding work has been done is that which is concerned with the processing of food. Some of this involves the use of stainless steel. Certain containers have been vastly improved by lining with this material which is applied in strips welded together and to the main body of the container.

A striking piece of work of a different nature concerned the repair of diffusion cells used in the production of sugar from beet. In the great factories engaged upon the important task of making sugar, when once the process is started it is continuous. That is to say it proceeds night and day, month in and month out until the autumn harvest of beet is reduced to its required components of sugar and residue dried pulp which is a valuable cattle food. In these circumstances any hitch in the smooth running of the complex plant would be serious, to put it mildly. The diffusion cells, to which reference has been made, are iron castings resembling huge cauldrons. The diameter is 6 ft., the height 3 ft. 2 ins. and each unit weighs 2 tons. Not only was the metal cracked extensively but some of the mounting lugs, which originally were integral with the main casting, were broken away entirely. As no spares were available there must be no element of doubt as to an utterly dependable result and in addition it was emphasised that the work had to be completed by a certain date not far distant. Barimar achieved a perfect and invisible repair well within the stipulated time and issued their usual money-back guarantee.

Prior to 1939 welding repair work was becoming an increasingly valuable export. A wide variety of engine components were received for attention from all over the world. The items most frequently shipped were crankshafts (some of large size belonging to powerful diesel engines) cylinder heads and blocks with a considerable proportion of precision cut gears from which the teeth had been broken away and often lost necessitating the 'growing' of new teeth by scientific welding methods.

This work for overseas users is being resumed and it is increasing steadily. It might be thought that the cost of a double shipment together with the time factor would render such a scheme impracticable except on a restricted scale. In many instances it is possible to complete the repairs and re-ship within a week of the damaged parts being received. Sometimes a great deal of time is saved because of the lengthy delay in obtaining many important components such as crankshafts, large crankcases and other major items. Although the cost of re-conditioning is very small when compared with the price of replacement, even so, the greatest saving is often that which follows upon the additional weeks and months that are frequently required to supply a new part.

Typical of this class of repair was the top half of a crankcase belonging to a three-cylinder Diesel engine operating a pump for a vital water supply. The casting is of massive proportions as it carries the cylinder liners and provides the jacketing. Across the end of the casting and running for about a third of its length on one side, was a crack. In addition to a full measure of strength being restored perfect alignment was imperative for without it the repair would be useless; moreover any error or even an increase beyond the estimated date of completion would create an extremely serious situation. The welding was completed well within the period promised, subjected to pressure tests far in excess of those reached during normal running conditions and has since fully justified the confidence that the owners had in the ability of Barimar to handle the difficult task successfully.

Equally exacting in its demands to the repair just described was the work carried out recently on the cylinder of a power hammer. The casting stripped weighs 5 tons and measures 10 ft. by 7 ft. and is 3 ft. 6 ins. across. The trouble was a crack extending more than half way up the bore

and production in a steel works was being held up pending repair. The welding was done horizontally but, if needs be, vertical and even overhead welding of cracks can be tackled successfully.

A feature of this job was that so neatly was the welding carried out that re-boring was not necessary and the casting was set up and put to work just as it was received from the hands of the Barimar operators.

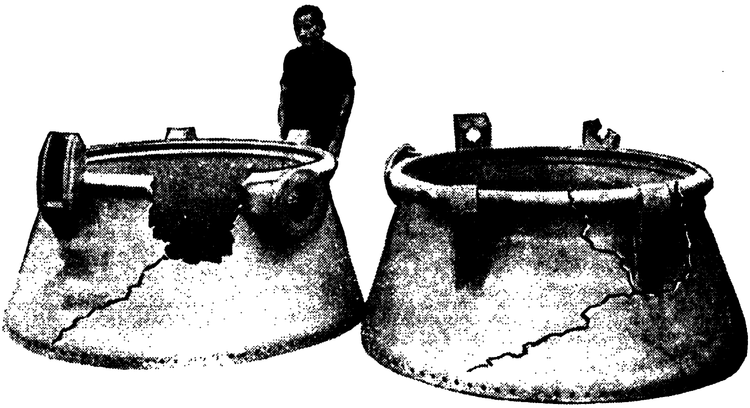

FIG. 1.—Two badly broken and cracked diffusion cells used in sugar beet manufacture. Weight 2 tons each.

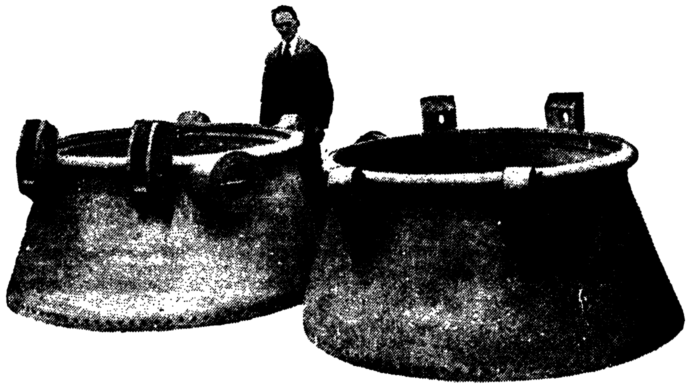

FIG. 2.—The 'cauldrons' after successful repair by scientific welding.

In these days of urgency scientific welding is accomplishing repair work the value of which it is impossible to compute. Sometimes the chances of a successful outcome seem so slender that some owners regard a breakdown as being hopeless from the start. This is not wise, for so remarkable is the progress that has been made that work regarded as being virtually impossible not long ago has now become almost commonplace.

MUREX ELECTRIC ARC WELDING EQUIPMENT AND ELECTRODES.

(Murex Welding Processes Ltd., Waltham Cross, Herts.)

A comparatively low voltage is required for electric arc welding, *e.g.* 50–60 volts if direct current is used at the arc, or 80–100 volts for alternating current supplies. In order to convert efficiently the power from an electrical supply to meet the requirements of arc welding, a motor generator equipment or a transformer must be used. These equipments, while reducing the mains voltage to that required for welding, must also have special volt/ampere characteristics to ensure arc stability. Further, a range of such characteristics is necessary so that a choice of welding current is available.

A typical volt/ampere characteristic curve of Murex generators and transformers is shown in fig. 1. The actual welding voltage in the case of metallic electrodes is generally between 20–35 volts, according to the size of electrode and current used. The curve shows a 'drooping characteristic,' *i.e.* as the load increases, the voltage 'falls' from the open circuit value to that required for

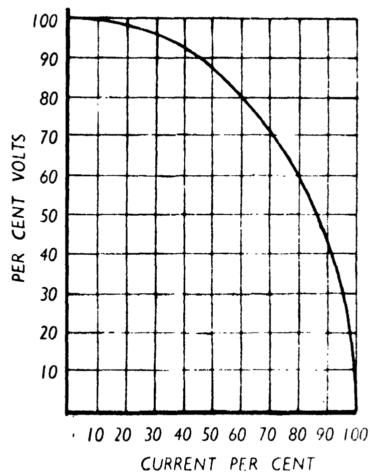

FIG. 1.—Typical Volt/Ampere Characteristic Curve of Murex Generators and Transformers.

welding. This characteristic is achieved by the design of the generator, or in the case of the transformer, by the design of the regulator or reactance.

The current required for welding is dependent upon the size of the electrode used, the following values being approximate for all makes and types :—

s.w.g.	16	14	12	10	8	6	4	5/16 in.	3/8 in. Electrode
Current	25	70	90	125	170	210	320	450	540 Amperes

The size of the electrode used is dependent on the plate thickness, the type of joint and welding technique employed. For example, a 16 or 14 s.w.g. electrode may be used on ⅛ in. thick plate, while on a 1 in. thick plate, a number of welding runs using perhaps 8, 6 and 4 s.w.g. electrodes may be necessary.

In a general engineering shop, a welding unit having an output of 15/400 amperes can therefore be considered essential.

Fig. 2 shows a typical 300/400 ampere Murex motor generator welding equipment. The motor and generator are built into one frame, the rotor of the motor and the armature of the generator being on the same shaft. The generator is of patent design having bifurcated poles which make possible a unique form of flux distribution. By this arrangement, the correct characteristic is obtained on a self-excited machine. The electrical efficiency is high and the time for recovery in voltage from short circuit to full open circuit is reduced to a minimum.

Two operator motor generator sets are also available and in this case, the two generators are built into one frame on which is mounted the control gear, the generators being coupled directly to a suitable motor. On a double operator equipment of this nature, provision is made for paralleling the two generators by means of a paralleling switch. Advantage can therefore be taken of the combined

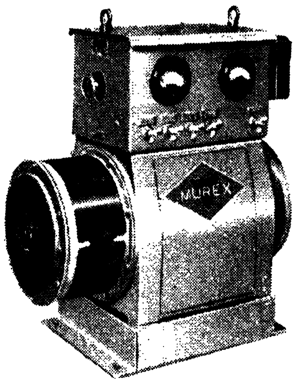

FIG. 2.—300/400 Ampere Motor Generator Equipment.

outputs of the generators to supply one operator on heavy work where large gauge electrodes are being employed for high-speed welding.

Where alternating current supply is available, the conversion of the electical power can be obtained by means of a transformer instead of a motor generator set. The portable unit illustrated in fig. 3 has an oil immersed transformer and regulator combined in one tank, space being

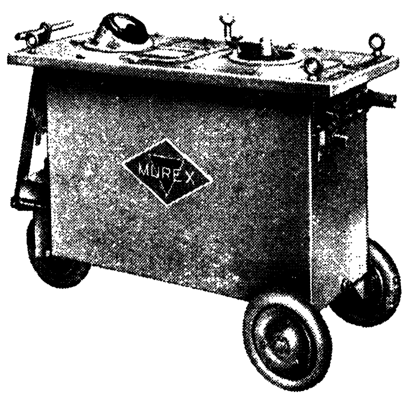

FIG. 3.—Portable 250 Ampere Transformer Equipment.

provided for inserting a capacitator for power factor correction. This equipment is designed to supply one operator with a current of 15 to 250 amperes for continuous hand welding.

Fig. 4 illustrates a three-operator transformer of the stationary type with regulators suitable for outdoor use.

All Murex transformers have a secondary open circuit voltage of 80 volts. Tappings are provided so that 100 volts can also be obtained specially for thin plate welding or for use in cases where the characteristics of the electrode require this voltage to maintain a stable arc.

On constructional work and sites where no electrical supply is available, petrol or diesel engine driven equipments are necessary. Fig. 5 illustrates a two operator unit, driven by a diesel engine running at 1,500 r.p.m., giving an output of 300 amperes per operator.

Motor generators, transformers and engine-driven equipments are available with outputs up to 600 amps per operator. All equipments can be arranged as stationary or portable units to meet the various site conditions.

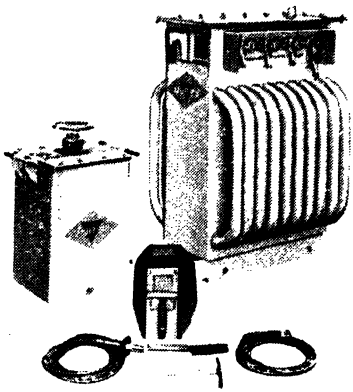

FIG. 4.—Multi-operator Static Transformer Equipment.

A comprehensive range of welder's accessories is also available including electrode holders, helmets and screens, spectacles and goggles, protective clothing in leather and asbestos, respirators, wire brushes, chipping hammers, flexible cable and tong test ammeters, etc.

Murex electrodes are manufactured for all classes of steel and non-ferrous metals. A number of special types are available for stainless steel, for bronze and for applications where hard surfaces

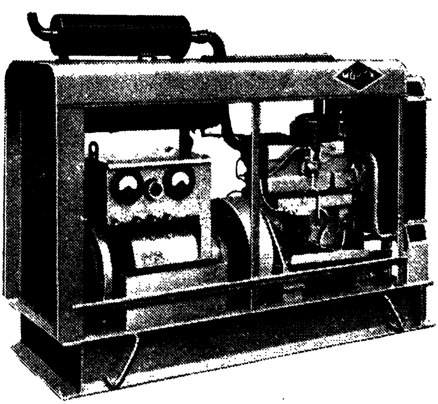

FIG. 5.—300/400 Ampere Diesel Engine Driven Equipment.

are required. This range of electrodes includes types approved by the British Admiralty and the Classification Societies for the welding of mild steel, high-tensile steels and also for pressure vessels. Special courses of instruction for welding operators, supervisors and designers are provided in the Murex Welding School attached to the manufacturing and research departments at Waltham Cross, Herts, England.

SECTION XXV

Fuels: Solid, Liquid and Gaseous.

Pulverisers.

THE CLARKE-CHAPMAN 'RESOLUTOR' PULVERISER.

(Clarke, Chapman & Co., Ltd., Gateshead on-Tyne.)

This pulveriser, see fig. 1, is a self-contained unit machine and obtains its product by the impact of renewable beaters attached to a rapidly revolving disc. The coal is fed into the machine from a hopper by a belt, the speed of which can be readily controlled. Entering the pulverising chamber the coal is caught up by the high-speed beaters, shattered to an extreme degree of fineness and

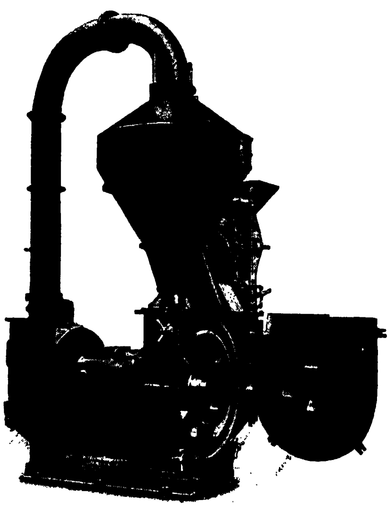

FIG 1.

drawn up by means of the action of a fan into a separating chamber. In this chamber an adjustable deflector returns any coarse coal for re-pulverisation, whilst the fine material is drawn off into the firing circuit. The 'Resolutor' pulveriser in sizes ranging up to 5 tons per hour is now successfully firing water-tube boilers, Lancashire boilers, marine boilers and furnaces of all descriptions. This pulveriser is also in use for firing cement kilns and for powdering various materials for industrial purposes.

THE CLARKE CHAPMAN RAYMOND BOWL MILL.

This pulveriser (fig. 2) comprises a milling unit and an exhauster fan both of which are driven by independent motors while the exhauster fan motor has variable speed control.

The milling unit consists of a slow speed revolving bowl upon the sides of which the coal is crushed to powder by rollers which have adjustable spring loading.

The upper portion of the mill casing embodies a classifier with adjustable louvres and deflector which allow only the finest of the fuel to pass to the exhauster fan and thence to the burners, while the coarse particles are returned to the bowl for further reduction. The raw coal being

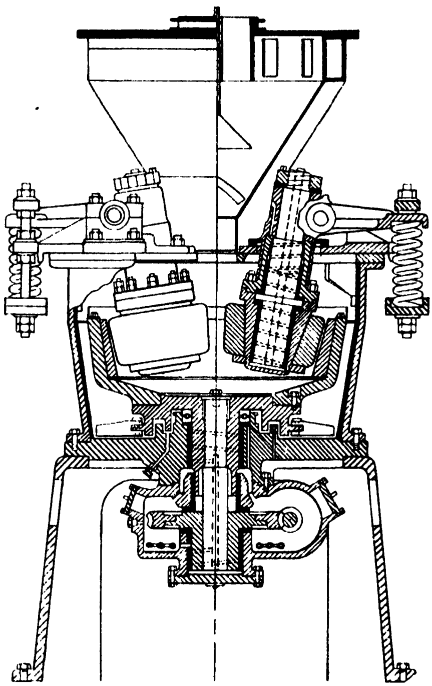

FIG. 2.

fed into the mill is mixed with the dry coarse returns from the classifier and due to this and the application of hot air, fuel containing a high percentage of moisture can be milled without difficulty.

To resist the wearing action of the coal, the bowl liner and crushing rollers are made of special metal while the casing is fitted with liners where necessary.

The exhauster fan is of robust construction with renewable volute sections.

The mill and fan units are so constructed that replacements can easily be made.

The adjustments of the crushing rollers and classifier controls can all be made from the outside while the plant is in operation.

The lubrication of the worm drive and bearings is by means of an enclosed circuit which ensures all parts being continuously lubricated.

The milling unit exhauster fan can be arranged so that both are driven by the same motor or each driven by separate motors in which case the exhauster fan motor can be of the variable speed type.

Pulverised Coal.

PULVERISED COAL FIRED BOILERS.

(International Combustion, Limited, Nineteen Woburn Place, London, W.C. 1.)

Lopulco Boilers.

The evolution of the Lopulco 'open furnace' type of boiler has taken place along with the progressive development of pulverised fuel firing and the result embodies all those features necessary to a combination of high availability and high efficiency.

Boiler and furnace are an integral steaming unit, the furnace being of such a shape as to provide maximum heat absorbing surface in relation to its cubic content. Full furnace cooling either of fin or plain tube construction is employed down to the ash hopper discharge and the burners are so positioned as to provide maximum temperature gradients without hot zones conducive to slag deposition.

The open outlet allows the use of a divided superheater, the front section of which is the semi-radiant wide pitched type and the need for baffles throughout the convection section of the boiler is reduced to a minimum if not dispensed with altogether. Dust pockets are provided before and after the lower drum so as to reduce all possibility of dust accumulation.

The circulation of the boiler is so arranged that the rear drum which is elevated in relation to the front has no active steam generating tubes entering, thus producing conditions most favourable to exceptional steam purity. It is thus possible to allow high rates of steam generation per foot of furnace width with corresponding high transfer rates and economy in construction.

The unit is suitable for the employment of the highest practicable air temperatures and is naturally suited to the high feed temperatures employed with multi-stage feed heating. High moisture and high ash content fuel can, therefore, be used to maximum advantage. This type of unit can be built for all ranges of pressure and evaporation but is naturally suited to high pressure and temperature conditions for high evaporations. Variants of this basic design can be offered with one or more drums for either pulverised or stoker firing to meeet any combination of fuel and steaming conditions which may be required.

The use of fin tubes for the furnace construction allows of the complete elimination of refractory materials on the fire side of the furnace and the minimum use of insulating medium. The Lopulco method of drum slinging is also applied where drum sizes are such as to set up binding stresses in the shell. Sling bands are forged integral with the shell in such positions as to reduce bending stresses to zero with the result that there is often an appreciable reduction in thickness and weight —a most important advantage for high pressure conditions.

Pulverised Fuel Firing.

The modern and almost universally used system of pulverised fuel firing is the 'Unit' system (fig. 2, p. 1190), where one or more mill units are direct coupled to the furnace burners and receive their drying medium direct from the boiler unit. When pulverised fuel firing was first introduced, the bunker system was used in which the fuel was dried (often in separate machines), pulverised, and delivered to a storage bunker from which it was fed to the burners by a multiplicity of feeders. This system had many drawbacks and the improvement in reliability and size development of the milling units together with the adoption of simultaneous drying and pulverising of the fuel has meant the virtual abandonment of the bunker system except for such classes of coal which make it essential to separate the burning and pulverising operation. In this country it is now only used for anthracite coal firing. In a similar process of evolution the use of the arch type of firing where the burners projected the coal and air mixture down into the furnace bottom with a U sweep up to the boiler outlet, has been virtually abandoned except for anthracite coals and replaced by horizontal burners.

In this type of burner the primary air and coal stream is surrounded by an envelope of secondary air in quantity sufficient to secure complete combustion. Centrifugal motion is imparted to these streams to give the widest possible air contact to the coal particles.

The burners can be arranged for forced draught and induced draught, and depending on the configuration of the furnace these burners may be arranged in one wall or in pairs in two opposed walls across the depth or width of the furnace.

A maximum degree of furnace turbulence can be secured by setting the burners in the corners of the furnace and directing the flame path to an imaginary circle in the centre of the furnace, With this arrangement the zone of maximum heat release and absorption is spread over the widest possible area and the minimum furnace exit temperature assured. Important advantages can be gained by making the corner burners controllable as regards elevation so that the flame zone can be raised or lowered at the will of the operator providing, in effect, an 'adjustable furnace,' in that the volume and absorption surfaces can be adjusted to the requirements of any grade of coal. By this means regulation of the furnace gas leaving temperature is possible, giving a primary control on the steam temperature and substantial control over slagging conditions both at the top and the bottom of the furnace.

Milling Plant.

The most commonly used type of mill for pulverised fuel firing is the medium speed ring roll mill.

In the Lopulco mill of this type, two large diameter rolls revolve on fixed axes against a horizontal driven table. The rolls are connected by a powerful spring gear which ensures equalisation

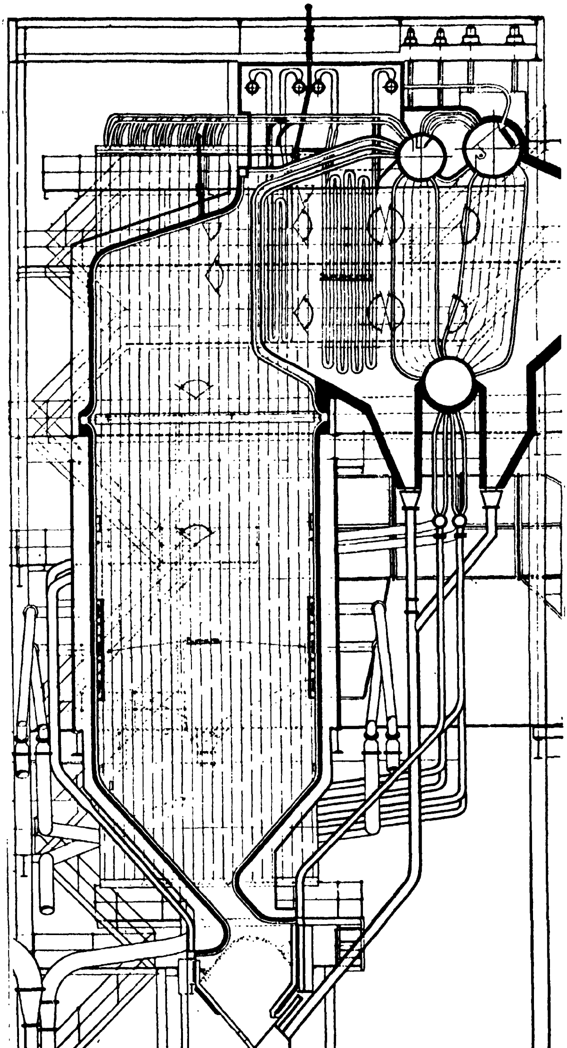

FIG. 1.—'Lopulco' Boiler.

of grinding effort and produces minimum power consumption. The flat grinding table allows for reversal after wear to obtain maximum use of metal before rejection. The driving unit is a self-

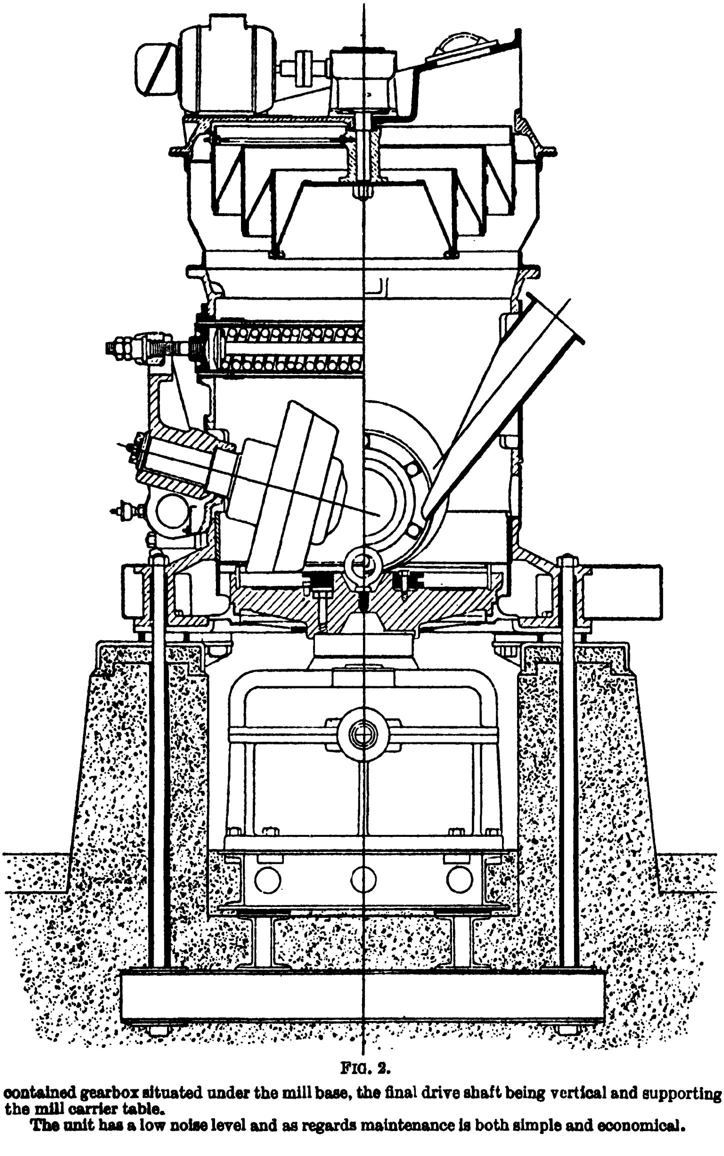

FIG. 2.

contained gearbox situated under the mill base, the final drive shaft being vertical and supporting the mill carrier table.

The unit has a low noise level and as regards maintenance is both simple and economical.

Separation is controlled by a rotary type separator housed directly over the grinding chamber and is of the variable speed type.

The grinding unit is completed by an exhauster fan which may be of the variable speed type or direct coupled to the mill drive.

Made in a number of sizes for outputs ranging between 2 and 16 tons per hour, this unit is particularly suitable for sustained peak running in power stations. Where peak loads are infrequent, high speed mills are often suitable especially for industrial boiler plants. The Impax Mill of this category is of the usual swing hammer type with coupled exhauster. A special feature is the variable speed rotating classifier, which gives a greatly improved fineness range over the static type. Higher in power and maintenance than the Lopulco Mill, it is low in capital cost and particularly suitable for firable coals.

The I.O. Ball Mill operates on the straight-through system with oversize return to the feed end. It is especially suited to grinding anthracite and refractory coals and has low maintenance. Its noise level and power consumption are high. When fitted with variable speed exhauster it can be used for unit firing.

Refuse Disposal Plants.

(Heenan & Froude Limited, Worcester.)

A few years ago the usual method of dealing with domestic refuse collected from houses, etc., was by complete incineration as an alternative to tipping on the land or dumping into the sea. A period followed in which the refuse was sorted over and materials of value salved and sold, the remainder being burnt or tipped. At the present time, in addition to these methods, screening machinery is provided which separates the dust from the refuse and enables cinders, tins, and other material of value to be picked out for sale whilst the remainder is burnt in an incinerator.

Where desirable, steam is raised for power purposes from the burning of the refuse, and electrical current may be generated, as in the large refuse destructor plant of the Glasgow Corporation at Govan, particulars of which are given elsewhere in this book.

In the diagram (p. 1192) are shown the six main stages of the 'Heenan System' of refuse disposal and various plants have been erected incorporating all or some only of the stages according to the local requirements or conditions.

Stage 1 comprises the delivery of the crude refuse from the refuse collecting vehicles into the receiving hopper, the travelling bottom of which discharges through a regulating device the right amount of refuse to supply the elevator or conveyor feeding the rotary screen.

In the screen, the dust is separated from the refuse and falls into a hopper underneath from which it is withdrawn as required and taken to the local tip or otherwise disposed of.

Stage 2 of the system comprises the removal of the cinders and small debris in the second part of the screen.

This material is also collected in a hopper and withdrawn as required. The cinders and debris may be treated to a further process in which the latter is separated, leaving clean cinder only and carrying the debris on to the incinerator for burning.

Stage 3 separates the iron and tin cans from the tailings leaving the screen, by means of electro-magnetic separation. The tins, etc., are picked up on the end plate of the screen, and, as they are carried round out of the magnetic field, drop off and fall down a chute to the baling press below where they are pressed into handy size bales weighing from 30 to 50 lb. each. These bales can be neatly stacked and stored until required for melting down at a steel works or treating otherwise.

In stage 4 the tailings from the rotary screen are conveyed on a slow-moving belt from which any further material of value is picked off by hand. This salvaged material is stored and disposed of at intervals. The remainder of the tailings pass on to stage 5, viz., to the incinerator into which they are fed by means of a movable tripper and chute for destruction. This tripper enables the cells to be automatically fed but when desired, or necessary, the tripper can deliver the refuse on to the feeding floor from which it can be hand shovelled into the top feed openings of the cells.

The incineration of the refuse produces hot gases which pass into the boiler in stage 6 of the system. A water tube type is the most suitable owing to its relatively large heating surface and free gas area.

These gases generate steam which can be usefully employed in the production of electrical power or for pumping water or sewage.

In many plants of the 'Heenan System' the first four stages are omitted and the whole of the refuse with the exception of the metals is incinerated for the full production of power.

Two pounds of steam and upwards can usually be obtained from each pound of refuse burnt and therefore an appreciable amount of power can be produced from the refuse of a fair-sized township with the added advantage that the objectionable and unstable refuse (which has in any case to be disposed of) is reduced to a valuable innocuous clinker.

From the boiler the gases pass into a chimney which has to be of sufficient height and area to overcome the gas resistance of the boiler, flues and furnace and to prevent back pressure in any part of the plant.

As each 1,000 persons produce about 15 cwts. of domestic refuse per day the plant illustrated would, if worked 8 hours only per day, be suitable for a township with a population of about 50,000 persons.

If worked for 16 or 24 hours the capacity of the plant could be correspondingly increased, but this would necessitate the provision of storage space for the refuse owing to the collection being usually restricted to one shift of 8 hours.

Gas Recorders.

(The 'W.R.' Patent CO_2 Indicator.)

(International Gas Detectors, Ltd. (Late W.R. Patents, Ltd.), Great Wilson Street, Leeds.)

The W.R. CO_2 or Combustion Indicator is an apparatus which continually, automatically, and accurately indicates the percentage of CO_2 which is passing through the flues at any hour of the day and night. With this Indicator installed on the boiler plant the percentage of CO_2 obtained can be seen at once, and the necessary steps taken to increase the amount and thus save fuel.

Fig. 1 shows the diagrammatic arrangement of the essential parts of the device. It can be used in all cases of combustion where any class of fuel is used, and where CO_2 is a product of this combustion. The arrangement adopted differs materially from other CO_2 indicators.

The method employed in the 'W.R.' CO_2 Recorder depends on the difference of pressure generated on the two sides of a porous pot, one side of which is exposed to flue gas whilst the other contains soda lime granules contained in a paper cylinder which absorbs the coming CO_2.

An aspirator, S, worked by the natural draught which it increases, is fixed at a point as near the chimney base as possible, and continually aspirates gases from the flue it is desired to keep under observation. The path of gases is shown by the arrows. They are first drawn through a filter F, and pass from thence into a chamber containing a porous pot, inside which is a dry reagent, R. The flow of gas is shown by continuous bubbling through water in vessel

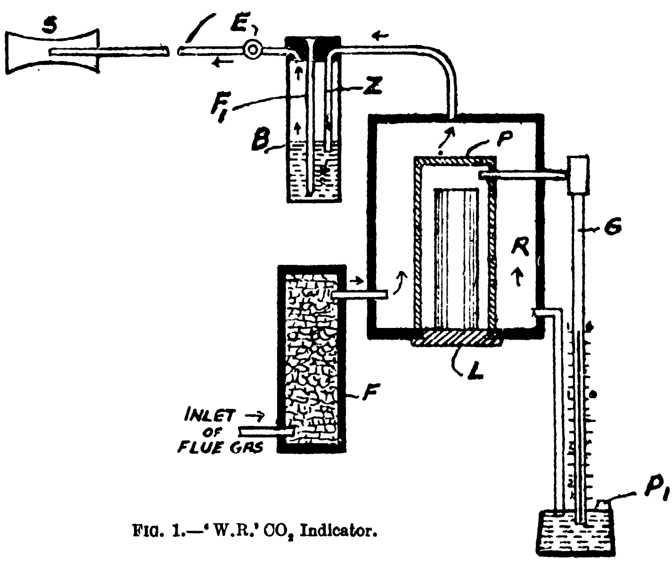

Fig. 1.—'W.R.' CO_2 Indicator.

B. A pipe connects the chamber with a vessel containing water into which dips one end of another pipe, G, the other end of which is taken into the inside of the porous pot. Some of the gases penetrate into the interior of this pot, and are absorbed by the reagent, with the result that a partial vacuum is formed. and the water is forced up the pipe G. The latter is provided with a scale so graduated that the percentage of CO_2 in the flue gases can be read.

The W.R. indicator is prompt in its action, having a lag of one minute only. Its deviation from absolute accuracy has been found to be only 0·1 per cent. It is well constructed; has no mechanical moving parts; is fireproof and foolproof, and can be worked by any boy of average intelligence. With each Indicator the manufacturers furnish a blue print showing the method of fitting to each particular boiler, also special detailed instructions for installing the apparatus, which operation can be completed in from four to six hours by any works' engineer or fitter. In cases where a recording graph is desired, one of a specially approved form can be supplied by International Gas Detectors, Ltd. The cartridges last 24 hours of continuous working.

SECTION XXVI

Electrical Engineering.

Electrical Instruments.

Insulation and Resistance Testing Instruments.

(*Evershed & Vignoles, Ltd., Acton Lane Works, Chiswick, London, W. 4.*)

The majority of electrical breakdowns and accidents are caused by defective insulation. Insulation failure can generally be avoided by systematic testing with a Megger or Meg Insulation Tester, but to guard against the dangers of a sudden accidental failure, the continuity of the earthing circuit should also be tested.

The values of insulation resistance and the tests required are laid down in the British Standard Specification for the particular apparatus, and the Institution of Electrical Engineers Regulations for the Electrical Equipment of Buildings (eleventh edition) gives the corresponding values of insulation and continuity resistance for completed installations and the tests required to verify these.

The principle of operation of the wee-Megger, Meg and Megger Insulation Testing Sets, described below, is represented in fig. 1. Each instrument contains a hand-driven direct current

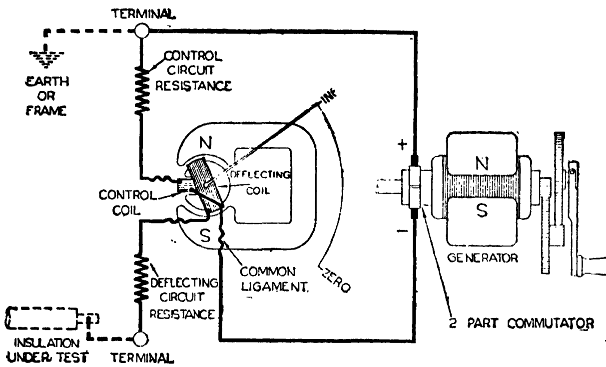

FIG. 1.

generator to supply the testing voltage, and a direct reading ohmmeter for measuring the value of the insulation resistance. The ohmmeter movement consists of two coils, the control coil and the deflecting coil, mounted at a fixed angle to one another on a common axle. Both coils are in parallel across the generator, the control coil being in series with a fixed resistance, and the deflecting coil in series with a second fixed resistance and with the resistance under test. The ratio of the currents in the two coils will therefore depend solely on the value of the resistance under test, since variations in the pressure generated, due to varying handle speeds, affect both coils in the same proportion. The deflection of the pointer depends on the ratio of the currents in the two coils and hence gives a true measurement of the resistance under test, the dials being calibrated in megohms and thousands of ohms.

The Meg and Megger Testing Sets (figs. 3 and 4) can be supplied with generators of the constant pressure type, having a special centrifugal friction clutch which ensures a constant testing voltage. Instruments fitted with this device should be used when testing the insulation of installations having considerable electrostatic capacity.

The ranges and uses for which the various types of instrument are recommended, are set out below.

Instruments for Measuring Insulation Resistance only.

The wee-Megger Tester (fig. 2) is suitable for testing house wiring, small motors, etc., operating on voltages not exceeding 250 volts.

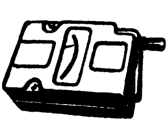

FIG. 2.

Testing voltages up to 500 volts.
Ranges up to 20 megohms.
Size 5¾ × 4 × 2½ in.
Weight 3 lb.

The Meg Insulation Tester (fig. 3) is recommended for testing power circuits, motors, etc., operating on 500 volts and for testing mains having moderate electrostatic capacity.

Testing voltages up to 1000 volts.
Ranges up to 2000 megohms.
Size $5\frac{1}{2} \times 9\frac{1}{4} \times 6\frac{1}{4}$ in.
Weight 7–9 lb.

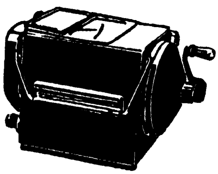

FIG. 3.

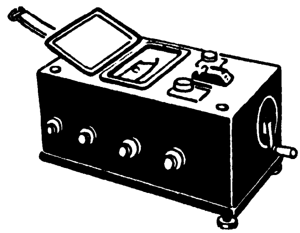

FIG. 4.

The Megger Testing Set (fig. 4) is recommended for testing high-tension equipment, transformers, mains, etc., and apparatus having a high degree of insulation and considerable electrostatic capacity.

Testing voltages up to 2500 volts.
Ranges up to 10,000 megohms.
Size $14 \times 8 \times 8$ in.
Weight 20 lb.

Special high range instrument :—

Testing voltage 5000 volts.
Range 20,000 megohms.
Size $18\frac{1}{2} \times 13\frac{3}{4} \times 10$ in.
Weight 60 lb.

INSTRUMENTS FOR MEASURING INSULATION AND CONDUCTOR RESISTANCES.

The Meg Insulation and Continuity Tester is similar to the Meg Insulation Tester, but contains a second scale of 0–100 ohms and a changeover switch enabling both the insulation resistance of an installation and the continuity of the lead sheathing or tubing to be measured.

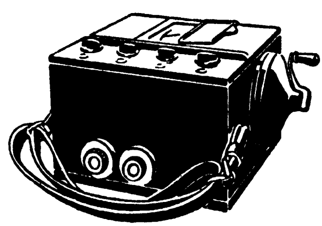

FIG. 5.

The Bridge-Meg Testing Set (fig. 5) combines in one case a constant pressure Meg Insulation Tester and a complete Wheatstone Bridge. It covers a wide range of resistance and is a suitable instrument for the maintenance engineer.

Testing voltages up to 1000 volts.
Range covered 0·01 ohm up to 200 megohms.
Size $7 \times 8\frac{3}{4} \times 12$ in.
Weight, $12\frac{3}{4}$ lb.

Mains operated Ohmmeters for routine measurements. The ohmmeter movements are mounted in switchboard pattern cases and arranged for operation on direct current mains or on alternating current mains through rectifiers.

Instruments for Measuring Earth Resistance.

The resistance of earth plates and other buried metal structures are of very great importance both from the point of view of the efficient operation of a system and of safety. The resistance must be maintained at a low value and should therefore be periodically measured.

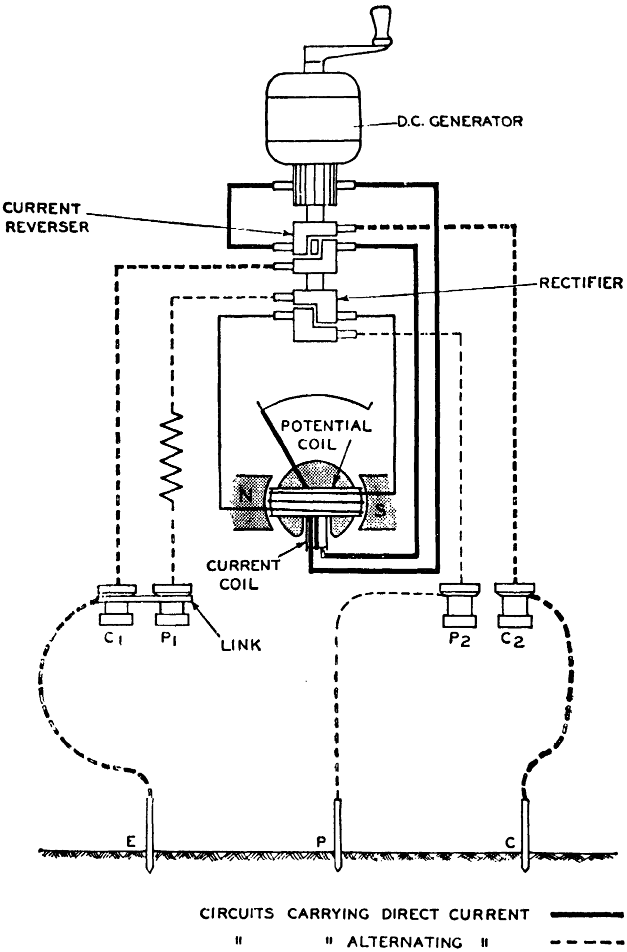

Fig. 6.

The Megger and Meg Earth Testers, which are similar in external appearance to the Megger and Meg Insulation Testing Sets, are used for this purpose.

Each instrument contains a hand-driven direct current generator and an ohmmeter of the moving coils type (fig. 6), one coil of which carries a current proportional to the testing current

and the other coil a current proportional to the potential difference between the earth electrode under test (E) and earth. The deflection of the ohmmeter which is proportional to the ratio of these currents gives the earth resistance directly in ohms. To avoid the effects of back E.M.F. and stray currents in the soil, a rotary current reverser and rectifier are incorporated so that the current in the soil is alternating whereas that in the ohmmeter is direct.

INSTRUMENTS FOR MEASURING LOW RESISTANCES ONLY.

These instruments each contain a direct reading ohmmeter of the moving coils type as fitted in the Megger and Meg Insulation Testers. but operate on low voltage.

The Megger Circuit Tester (fig. 7) which is a small direct reading portable ohmmeter operated from a self-contained 4½-volt dry battery, is suitable for measuring conductor resistance, for testing motor windings and continuity of sheathing, and for tracing circuits.

Range covered, 0–200,000 ohms.
Size 5⅝ × 4 × 2¼ in.
Weight 2 lb.

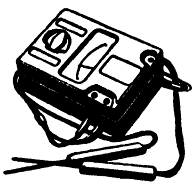

FIG. 7.

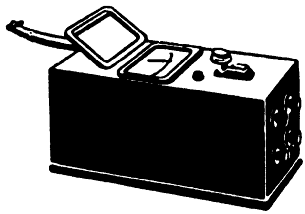

FIG. 8.

The Ducter Low Resistance Testing Set (fig. 8) is a direct reading portable instrument operating from an external alkaline battery. It is provided with a range switch giving four or five different ranges, and measures from 1 microhm to 5 ohms. It is suitable for testing switch contacts, rail bonds, windings of series motors, etc.

INSTRUMENTS FOR WATER TESTING.

The electrical conductivity of a dilute solution is proportional to the amount of inorganic impurity which is present in the water and thus can be used as an indication of the amount of the impurity.

The Dionic Water Tester is a portable equipment by means of which the conductivity of a sample of water can be quickly and accurately determined. Since this conductivity varies considerably with temperature, means are provided to correct for temperature variations.

The presence of impurities in boiler feed water condensate, etc., is of very great importance and it is often necessary to have a continuous indication or record of the state of this water.

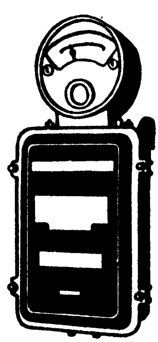

FIG. 9.

The Dionic Water Purity Meter or Salinometer (fig. 9) has been designed for this purpose, and has been extensively used both on board ship and in power stations for giving a continuous indication and chart record of the condition of the boiler feed water.

Coolers.

TUBULAR AIR COOLER.

(Heenan and Froude, Limited, Worcester, England.)

This cooler is suitable for general industrial applications calling for the cooling of air or gases without bringing them into direct contact with the cooling medium, and is widely employed in conjunction with the ventilation of alternators and motors. In the latter case the air circulates between air outlet and air inlet of alternator, in a closed circuit in which is placed the air-cooling unit. The latter consists of a nest of tubes held between tube plates, the tube joints being formed by ferrules and packing. On the air side the tubes are provided with highly efficient heat-exchange elements which are strongly soldered to the tubes, while the bores of the latter communicate with headers provided with baffles to promote the most efficient circulation of the cooling water.

For alternator work secondary tube plates are incorporated behind the main tube plates, the space between forming patented dead air spaces which trap any water which may leak from the tube ferrules and carry it away to drain, thus eliminating the possibility of loose moisture being carried through with the air into the alternator windings.

The water headers are normally fitted with inspection doors arranged so that they can be opened for access to the tubes for cleaning purposes without breaking the water piping joints.

To cover such emergencies as the cooling water supply failing, it is usual to incorporate in the ducting system inter-connected dampers by which the cooler can be isolated and the alternator caused to work on 'open circuit'; patented layouts of damper gear are available which can be incorporated in practically any installation.

Electro-mechanical Brakes.

(Elliston, Evans & Jackson, Ltd., 24 Ray Street, E.C. 1.)

This firm, which has a wide and long-established experience as makers of high-class electro-mechanical brakes for all varieties of application, considers that special attention should be paid to the following characteristics governing construction and design. They will be glad to deal with any problems arising from the use or prospective use or application of any form of electro-mechanical brakes.

Electro-mechanical brakes are used in connection with a variety of electrically driven machines such as lifts, cranes, hoists, elevators, conveyors, rolling mills, paper reeling, slipways, presses, machine tools, etc., where either a quick 'stop' or adjustable gradual 'stop' is desired, when the power is cut off, either intentionally or unintentionally.

These brakes consist primarily of an electro-magnet, which operates the brake blocks through a system of levers or other medium. The magnet is so arranged that when the current is applied the magnet is energised and lifts the brake blocks from the drum. If for any reason the current is cut off the magnet is de-energised and the brake blocks are pressed against the drum, the requisite pressure being obtained by springs, weights, or a combination of each.

The brakes are quite automatic in action; thus, in the case of an electrically driven crane, as soon as the driver applies the current to the motor to raise the load the brake is automatically released, and when he switches off the current to stop the brake is immediately applied. Should for any reason the supply current fail the brake automatically goes on and takes charge of the load.

It is desirable that an electro-mechanical brake should have the following features: compactness of design, robust construction, few and simple working parts, easy adjustment for brake shoes and pressure exerted by same. Coils should be liberally rated, well insulated, and protected from mechanical injury, and so placed that they are not likely to be damaged by oil exuding from the machine. The brake linings should be readily renewable. Brakes can now be obtained fitted with shoes which are self-adjusting for wear. These obviate the necessity of making frequent adjustments to compensate for the wear of the linings. This is a most important consideration when A.C. magnets are used, as these have a limited stroke. If springs are used, they should be of the compression pattern. Some form of dashpot, either separate from or embodied in the magnet, should be fitted which is adjustable in both directions to enable the braking effect to be gradually applied or released. Further, it is important to ensure that the shoe-linings and magnet are properly proportioned for the work to be done, *e.g.* a brake having a given torque when used on a busy dock crane would not be the most economical type when used as an emergency brake on some forms of conveyor or rubber machinery. In each case the magnet would be rated for continuous duty, but, whereas in the former case the shoes might be applied one hundred times or more per hour for several hours a day, in the latter they would probably be applied once or twice a day only.

Cable Reels.

SELF-WINDING ELECTRIC CABLE REELS.

NEW 'TRAILER' DESIGNS FOR MACHINE TOOLS

(Power House Components Ltd. King Street, Nottingham.)

For all electrically driven equipment involving position movement, including for example machine tools, the 'Wayne' self-winding electric cable reel has a number of advantages. In the standard form it consists of a metal rotating reel on which the cable winds or unwinds, under the operation of a spring mechanism in an enclosed casing, on the same principle as the spring blind. By this means suitable tension is maintained without any undue slack or sag.

These self-winding reels, a production of Power House Components Ltd., King Street, Nottingham, carrying the general trade mark 'P.H.C.' and under the direction of David Rushworth, are available in nine types, according to the length and diameter of the cable used, that is the 'Baby' (for ordinary twin lighting flex), 'Standard;' 'Major 10/3,' 'Major 12/3,' 'Super 12/515,' 'Super 15/6,' 'Super 19/4,' 'Super 19/9,' 'Goliath' and 'Mammoth.' The latter, however, being the largest, mostly used for loaders, cranes and quarry work, differs from the other designs in that the return motion, because of the great weight of the cables, 2½–3 ins. diameter, is sometimes carried out by hand-operation wind instead of a spring. For long travel machine tools the 'Super' (0·625–1·25 in. diameter) and the 'Major' (0·30–0·625 in. diameter) are chiefly used, as also for overhead cranes, runways, and magnetic cranes and welding apparatus.

In general the standard reels are attached to a ceiling, wall, girder, or convenient part of a machine by a flange plate, and when the pay-out is not in a straight line are of the swivelling type, turning on a pivot, with a cable guide. Housed at the side (or both sides) and totally enclosed is the slip-ring gear, consisting of a stout ebonite disc carrying the slip rings, varying in

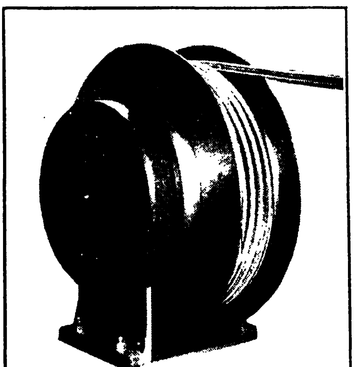

FIG. 1.

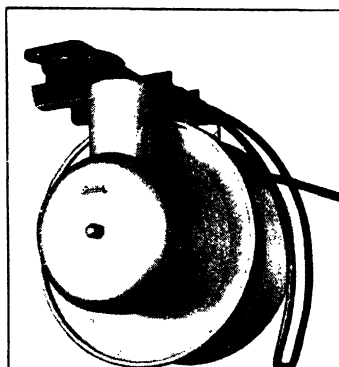

FIG. 2.

number to correspond to the cores of the cable, made of a special lead brass. The current pick-up standard plungers are of metal composition forming easily replaceable tips. They have conductivity as well as resistance to wear and facilitate maintenance work, whilst the spring, of the necessary size and strength to give ample margin for the duty, is of high-grade ribbon steel. Originally the pick-up plunger tips were of silver, but this is now used for light duty only.

Now there has been placed on the market a new 'trailer' design, available for the 'Major' and 'Super' sizes (0·5 in. and 0·7 in. cable respectively). This is a double acting or 'dual' reel, two sets of cable being accommodated and paid out in opposite directions. Consequently the new reel can be placed in the centre of the work, as in machine tools, for example, and double the amount of cable is handled because the pay-out action is in two directions at the same time, whilst electric sliprings and contact gear are eliminated. It is particularly suitable for long runways and similar applications. A modified design of roller swivel or round-about head has been

introduced which is suitable also for reels for protection against dust and combustible and explosive gases, which will take the complete range of reels up to the 'Mammoth' with 2 in. cables. This runs on a series of roller bearings with the casing attached to a flat top or cover, turning round at every angle, whilst the cable enters and leaves by a long gas-tight and dust-tight seal gland.

Much interest attaches to another modification, the totally enclosed type with a cable sealing gland in the baseplate which is suitable for operation in an explosive or inflammable atmosphere. Originally the enclosed design embodied a semi-circular steel cover totally covering the whole arrangement, the cable entering through a gas-tight gland at the top. Now, however, in the latest modification, the gas-tight gland is in the bottom cover with the cable entering or leaving from underneath, so that the cover can be removed for inspection and replacement without interfering with the cable and sealing joint.

Another specialised application is a motor turntable fire escape. For example, in one of the latest 'Merryweather' (London) escapes there is fitted for the telephone a 'Wayne' Super 19/4 type self-winding reel which handles 105 ft. of 4-core cable ⅜ in. overall diameter which operates the telephones at the top of the escape ladders, the cable winding or unwinding automatically as the ladders are elevated or the reverse, with no fear of entanglement or damage.

Finally mention may be made of still another modification, that is the 'Wayne' self-winding hose reel for dealing with rubber or canvas hose for general water supply. This is on exactly the same principle as for cables, and enables the hose always to be wound up neatly when not in use, without any trailing of long loose lengths of hose on the ground, subject to wear and tear and general deterioration. In each case the reel is designed for the specific conditions of an application, and any size of hose for use with normal pressures can be operated. A further application for these reels is the flame-proof contactless type for special 'foam' and other fire extinguishing liquid, using rubber hose up to 1½ in. diameter.

For flame-proof requirements or conditions where grit and moisture are found in such quantities as to make normal slip-ring gear unsuitable, a special range of Wayne Reels has also been introduced under the heading of 'Wayne' trailer type reel, which can be supplied in both moving and fixed designs, and also the Wayne twin-coil type reel; this is especially suitable for short lengths of cable.

With the era of post-war conditions many new demands are being set up for these reels, and a number of new designs are about to be placed on the market to cope with specialised requirements, and it is interesting to know that many of the designs will be readily adaptable to meet a wide variety of requirements which are envisaged in the next few years.

To assist Works' Safety Officers a Consulting Service is now available under the personal supervision of Mr. David Rushworth, the patentee and designer of Wayne Reels.

SECTION XXVII

PART II

Steam Generating Plant.

Boiler Design—Superheaters—Stokers—Electrostatic Precipitation—Feed Water Treatment—Scale and Corrosion—Boiler Fittings—Valves—Packing.

THE CLARKE-CHAPMAN WATER-TUBE BOILER.

(Clarke, Chapman & Co., Ltd.)

A Clarke-Chapman Water-tube Boiler is illustrated in fig. 1 (p. 1202), and consists of four drums and three banks of water-tubes, the top and bottom drums being connected together by steam and water circulating tubes. All the tubes are expanded directly into the drums.

The large and accessible superheater chamber between the first and second bank of water-tubes, contains a nearly vertical suspended superheater, consisting of a number of closely spaced multiple-loop tubes which are expanded directly into the circular superheater headers, housed in a separate easily accessible casing immediately above the boiler.

A large stoker-fired combustion chamber is provided, the side and front walls being water-cooled by means of plain tubing, the lower ends of the tubes being expanded directly into square section water-boxes, whilst the upper ends are either expanded directly into the front steam and water separating drum, or to top headers having connecting pipes leading to this drum. The lower headers of the water-walls are fed by means of downcomers from the boiler lower rear water drum. Suspended arches of refractory material are provided at the front and rear walls of the combustion chambers.

A steam receiver, or dome, running the full width of the boiler, is provided immediately above the rear steam drum, and connected thereto by a series of nearly vertical tubes expanded into each drum plate, any accumulation of moisture being permitted to drain freely back to the water in the boiler. The steam passes from the steam receiver into the superheater inlet header via a steam and water separator or dryer, fitted to the highest point inside the receiver.

At the rear of the boiler is placed the well-proportioned economiser, consisting of four banks of straight horizontal steel tubing, provided with cast iron gills or fins, giving extended heating surface, equal to about six times the surface of bare tubing. The steel economiser tubes are connected together at their ends by means of U type connecting tubes, row by row, so that the feed water fed into the economiser inlet header at the coolest end, travels onwards row by row of tubes, until it reaches the outlet header at the hottest end, before being passed on to the feed check valve at the boiler rear top drum. By-pass dampers are arranged so that the hot gases may be caused to pass directly into the fan inlet ducting when required.

The mechanical 'travelling' grate stoker is of large capacity, and provided with a forced draught fan. The stoker is so arranged that regular and even combustion can be secured over the grate surface under all combustion conditions, thus resulting in maximum output and a high combustion efficiency. The fuel is stored in a bunker just outside the boiler house and is fed to the stoker coal chutes by means of a suitable conveyor.

After combustion is completed the ash and clinker from the various hoppers is conveyed outside the boiler house by means of a water-immersed travelling conveyor.

An induced draught fan and dust collector is mounted above the boiler on the fan platform which also carries the boiler chimney for discharging the spent gases to the atmosphere.

All the pressure parts of the boiler are suspended freely on steelwork independent of the boiler house structure, with freedom for expansion everywhere. The combustion chamber brickwork is supported off the firing floor steelwork integral with the boiler structure and is free to expand in all directions thus avoiding cracking or dislocation of the brickwork. The firing floor steelwork also carries the weight of the stoker and hoppers. The large basement below the firing floor contains the F.D. fan, ash conveyor, various hoppers and turbine condensing water circulating pipes. Suitable arrangements are also provided for handling the ash and climker when the ash conveyor is not working.

By simply removing the manhole covers from the boiler drum ends, access is obtained to the whole of the boiler water-tubes, which may thus be easily and conveniently examined and cleaned.

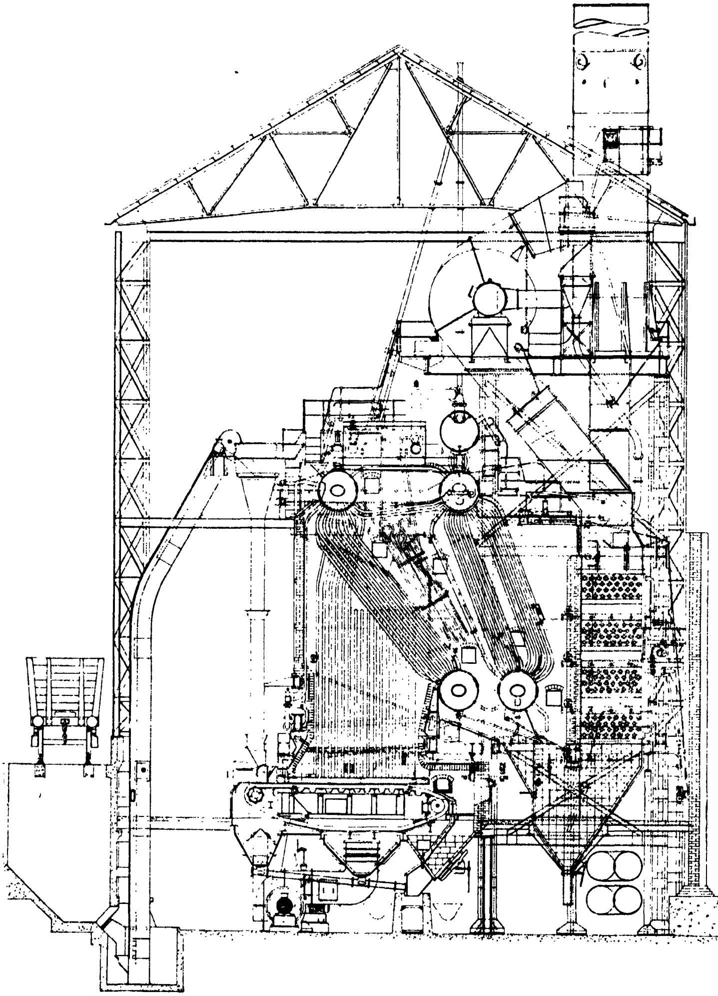

FIG. 1.—Clarke-Chapman Four-drum Water-tube Boiler.

Replacements of any individual tube when required may be easily and quickly effected. Inspection and cleaning of the whole of the gas side of the pressure parts is conveniently carried out by access to the spacious chambers surrounding the tube banks; suitable access doors being provided.

Daily shift cleaning of the whole of the heating surfaces is carried out by means of steam soot blowers, arranged at convenient points throughout the boiler, superheater and economiser tubing. Suitable soot and dust pockets of ample capacity are provided with convenient chutes for its removal.

The radiant-heat surface of the boiler is large and carries out a big proportion of the boiler evaporation. The convection heat surface is provided with suitable gas baffles, the area of the different passes being such that a gradually increased gas velocity is obtained ensuring maximum heat abstraction from the gases before entering the economiser.

Radiation of heat from the boiler is reduced to almost nil as the whole of the boiler-brickwork is covered with a steel casing suitably lagged by heat insulating material.

The multiple drums and water-tubing holds a large amount of contained water and heat reserve, and the extensive water level surface results in easy release of the steam and prevention of priming.

The boiler water has a well defined circulation; the feed water normally passes down the rear bank of tubes into the lower rear drum, and thence across to the lower front drum, rising up the front bank of tubes which comprises the main generating portion of the boiler. The steam generated passes from the front to the rear drum by way of the steam connecting tubes, whilst the water similarly passes to the rear drum by way of the water connectors.

The second bank of tubes are the downcomers, these with the front bank and connectors constituting the circuit. The gases and water flow in opposite directions, or counter flow, thus ensuring maximum circulating efficiency, and heat extraction.

It will be observed that the high hydraulic head available at the water walls is conducive to very effective steam and water circulation, the head being measured from the water level in the rear top drum to the inlet at the lower water boxes. By these means there is no possibility of the tubing in the hottest zone of the boiler being starved of water supply to make up the very rapid evaporation of the water walls. Similarly the front bank of boiler tubes is well supplied with water to keep pace with the evaporation from radiant heat surface.

The whole unit is conveniently operated and access is available to all parts of the boiler by carefully arranged ladders and platforms. A boiler control panel containing the necessary instruments for efficient operation is placed on the firing floor at the front of the boiler.

Clarke-Chapman Tri-drum Water-tube Boiler.

The Clarke, Chapman Tri-drum Water-tube Boiler is shown in fig. 2, the main features differing from the boiler shown in the previous figure consisting in the provision of an air pre-heater placed in the path of the gases immediately after the economiser, and supplying heated air for the combustion of the fuel; a secondary air fan supplying a strong blast of heated air above the stoker both from the rear and front of the combustion chamber; water-cooled walls to the four sides of the furnace the tubes being covered by Bailey cast iron blocks; primary and secondary controllable superheater; 3-tier square-finned tube economiser; coal bunker integral with the boiler house with coal weigher and travelling coal chutes to the stoker hoppers; bucket coal conveyors; separate house containing the F.D. and I.D. fans, the air to the F.D. fan being drawn immediately from above the top of the boiler and delivered by means of insulated hot air ducting to stoker; an annexe containing the steam and electric boiler feed pumps, a large basement, the ash and clinkers being removed by suitable trolleys; dual F.D. and I.D. fans and secondary fans; and external gas flue at roof leading to independent brick chimney adjacent to the boiler house.

The instrument panel containing the various pressure gauges, draught gauges, pyrometers, CO_2 meter, etc., being mounted at operating floor level and in front of the boiler.

In this case an even larger amount of radiant-heat surface is provided and the combustion chamber is of large capacity, capable of utilising a very large heat release per cubic foot. For soot blowing both gun type and multiple nozzle type steam blowers are provided and arranged to be operated in the most efficient sequence.

The water and gas circulation is similar to that of fig. 1, but additional baffles are provided at the rear bank to give additional travel to the feed water making for a very effective high temperature feed heater.

The whole plant has been arranged to give maximum thermal efficiency.

'Stefco-Wildish' Steam Separator and Dryer.

(Clarke, Chapman & Co., Ltd.)

The 'Stefco-Wildish' Patent Steam Separator is designed upon the basic principle of specific gravity, and arranged to replace the ordinary anti-priming pipe in a boiler. Solids, in the form of impurities and scale-forming matter, are heavier than steam, and in continually splitting up

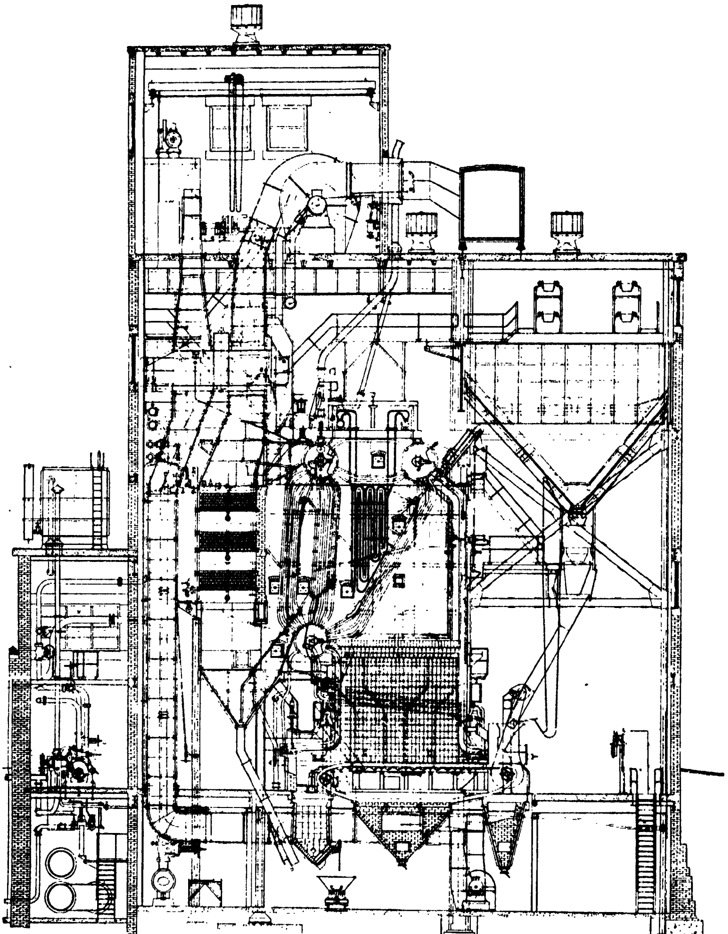

FIG. 2.—Clarke-Chapman Tri-drum Water-tube Boiler.

the volume of steam passing through the 'Stefco-Wildish' separator, as also by changing the direction of flow, the impurities, scale-forming matter and moisture content of the steam are precipitated in such a manner, and under such conditions that they may be easily discharged from the boiler.

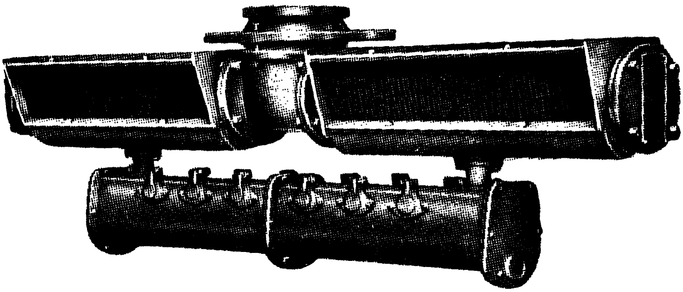

FIG. 3.—Stefco-Wildish Steam Separator as fitted in Boiler.

The design and outstanding features will be clear upon reference to figs. 3 and 4. The apparatus is so designed that by detaching the container (D) and the drain, it will pass through a standard oval manhole 15 ins. × 11 ins.

When in position the separator is attached to the boiler or drum shell immediately beneath the main steam outlet or stand-pipe. Fig. 4 shows the patented construction of the baffles, angled to the direction of flow of the steam, giving even better separation than vertical baffles due to the velocity of the steam assisting the separation. The impurities, solids and moisture are precipitated into container (D) fitted with flap valves which permit the return of the separated

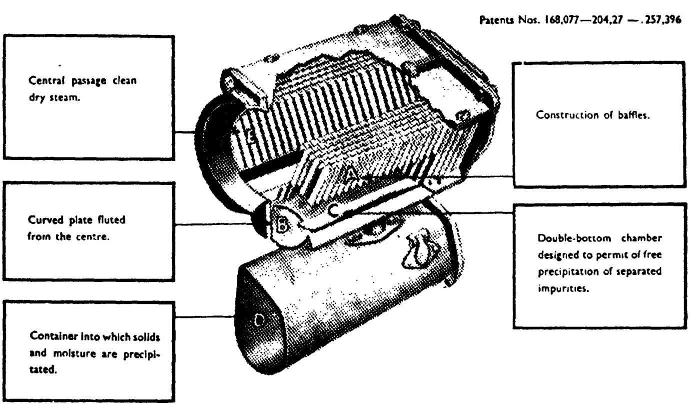

FIG. 4.—Showing Internal Construction.

water to the boiler at boiler temperature, while the heavier recovered sediment collects in the bottom of the vessel and by means of a connection through the drum shell may be blown out while the boiler is in operation.

The moisture and scale-forming matter that has been separated and collected is prevented, under surging and priming conditions in the boiler, from being drawn back and entrained along with the steam.

Other separators embodying the 'Stefco-Wildish' patents and suitable for fitting in pipe lines, are also made and are suitable for dealing with steam or air.

The Cochran Boiler.

(Cochran & Co., Annan, Ltd., Annan, Scotland.)

The boilers (fig. 1, p. 1207) are used very largely both ashore and afloat; the advantages claimed for them over other kinds for land use and export consist, principally, in great economy of space, in not requiring any brickwork setting, in having a large amount of highly effective heating surface, and in being very economical in fuel, besides being accessible for cleaning and repairs outside and inside.

For winch boilers this type contains the advantages of the cross-tube boiler and the horizontal boiler without their disadvantages, and has been found the most suitable for large passenger, mail, and cargo steamers.

The boilers are made in a range of standard sizes, as per the following Table, which gives particulars of their standard dimensions and normal evaporations.

Evaporation of Cochran Boilers.

No.	Particulars of Boiler.							Normal Steaming.					No.

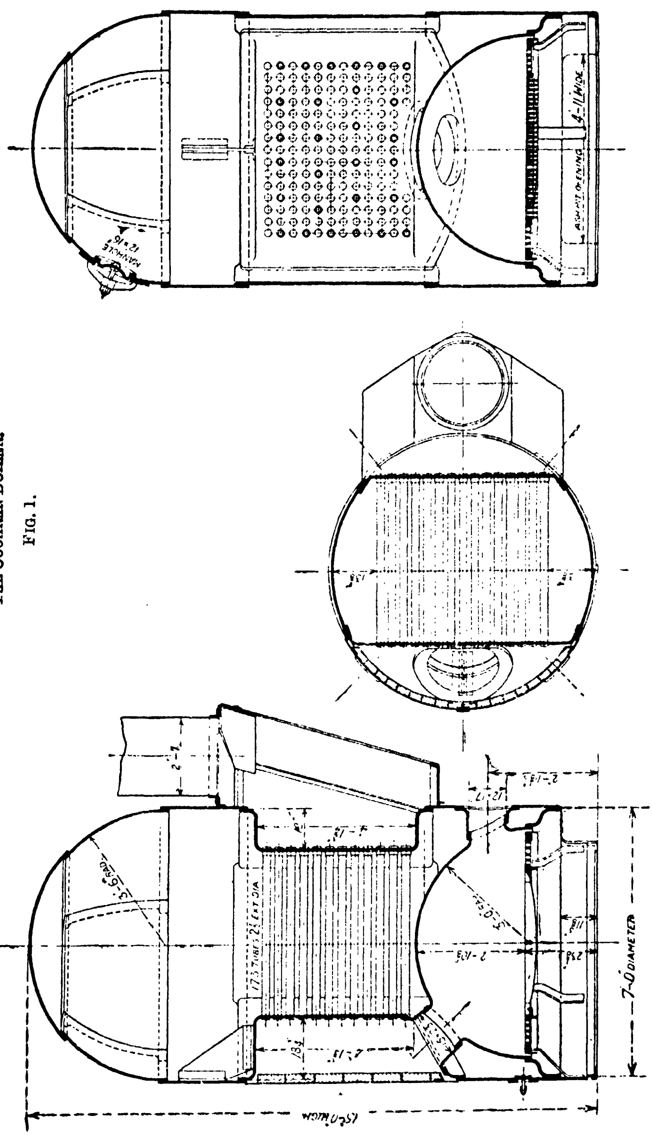
Boilers are numbered consecutively 1 (3 ft. 0 in.) to 23 (9 ft. 0 in.).



THE COCHRAN BOILER.

FIG. 1.

In addition to the range of standard sizes detailed in the above table, the 'Cochranette' Boiler, 2 ft. 6 in. dia. × 5 ft. 6 in. high × 25 sq. ft. heating surface, is built to stock in the one size only, for 100 lbs. per sq. in. working pressure. Also Cochran boilers are now constructed for the utilisation of Diesel engine exhaust gases only, and composite types for simultaneous use of exhaust gas and oil firing.

Cochran Diesel Exhaust-Gas Fired Boilers.

From the illustration (fig. 2) it will be seen that the principal advantages of the Standard Cochran design are incorporated in the exhaust gas boiler, including the feature of accessibility to all internal parts for cleaning and examination, which is essential for the maintenance of maximum heat transfer efficiency.

It will be readily appreciated that owing to the variety in sizes and types of Diesel engines available, it is not practicable to publish exhaustive tables of standard waste heat boilers, and that each individual case must be studied on its merits.

When considering a boiler for the utilisation of exhaust gases from Diesel engines, three methods suggest themselves :—

1. To use a Cochran Composite Boiler which has been designed to extract the maximum heat from the exhaust gases and can be fired simultaneously by oil fuel. For marine purposes, when the exhaust gas is used to raise steam for working a ship's auxiliary such as a dynamo or steering gear, this arrangement is essential, owing to the fact that it is sometimes necessary for the engine to be slowed down in fog, etc., with a consequent falling-off in temperature of the exhaust gases and steam raised.

2. To use a boiler designed to deal with exhaust gases only. The size of boiler to be used with a particular engine depends on the type of engine (2- or 4-stroke) and the quantity of exhaust gases. As a general rule the temperature of the exhaust gases from a 4-stroke engine will be approximately 750° F. and from a 2-stroke 550° F., and the weight of exhaust gases 14 lbs. per b.h.p./hr. for a 4-stroke engine, and 20 lbs. b.h.p./hr. for a 2-stroke engine.

3. To pass the exhaust gases through a standard boiler having tubes of diameter smaller than standard. With this arrangement the boiler is limited in use, in that it is only possible to raise steam alternatively, either by exhaust gas or oil firing. Steam raised in the standard boiler by exhaust gases will be less than with a boiler especially designed for the purpose. A special gas-tight construction is necessary for the furnace door and casings.

Boiler Diameter.	Overall Length.	No. of Flues.	Diameter of Flues.	Maximum Working Pressure in lbs./sq. in.	Normal Evaporation in lbs./hour from feed at 60° F.	Normal Evaporation in lbs./hour from and at 212° F.
ft. in.	ft. in.		ft. in.			
6 6	18 7	1	2 9	250	4,800	5,800
7 0	21 7	1	3 0	250	5,700	6,800
7 6	21 7	1	3 6	250	6,700	8,000
8 0	21 7	1	4 0	225	7,600	9,100
9 0	22 7	1	4 6	200	8,500	10,200
9 0	22 7	2	2 9	250	10,400	12,500
9 6	22 7	2	3 0	250	11,300	13,600
10 6	22 7	2	3 6	250	13,300	16,000
11 6	22 7	2	4 0	225	15,200	18,200
11 9	22 7	3	3 0	250	17,100	20,500
12 6	22 7	3	3 6	250	20,000	24,000
13 0	22 7	4	3 0	250	22,900	27,500
13 6	22 7	4	3 3	250	25,000	30,000

The above ratings are based on the assumption that automatic stokers with self-cleaning grates are fitted and fired with suitable coal.

The high rate of extraction of heat from gases passing through the patent 'Sinuflo' tube has made possible the design of a high duty boiler of the simple dry-back, return-tube type in which a high efficiency can be obtained without recourse to such aids to efficiency as double passes of tubes, external ducts, air preheaters and economisers.

Owing to the high tube efficiency of the 'Sinuflo' design of tube, it is claimed to be possible to work the boiler with induced draught and very heavy loads without the temperature of the gases becoming excessive. Moreover, it has been found that the frictional resistance to the flow of gases through a 'Sinuflo' tube is less than through an equivalent straight tube, *i.e.* a straight tube that would give the same temperature drop in the gases between entry and exit. Consequently, no increase in fan power is required to give the rated outputs.

The following distinctive features are incorporated (see fig. 3, p. 1209):

(1) The flues are made up, each with a waisted section, giving on the water side access to the whole of the flues and the shell of the boiler and causing on the fire side turbulence of the gases and rapid combustion.

(2) A wide space is provided between the tube nests and the flues, which gives the necessary flexibility for breathing which is regarded by builders of Scotch marine boilers as so essential if leakage troubles due to the unequal expansion and contraction of the flues relatively to the tubes are to be obviated.

(3) The tubes are fixed at wider intervals than is customary in return-tube boilers, thus allowing ample space between them for circulation of the water, and ensuring adequate cooling of the back tube plate.

(4) To eliminate the possibility of leakage down the threads of the longitudinal bar stays, solid flanged forgings are used for attachment to the tube plates, each forging having a blind hole screwed internally to take the bar stay and having its flange riveted to the end plate.

(5) The difference of expansion between the fire tubes and stay tubes due to different thicknesses of metal reduces internal strains, as the 'Sinuflo' tubes are less rigid longitudinally than ordinary tubes.

The Combustion Chamber.

The combustion chamber casing is of mild steel plate and forms an air-tight extension to the boiler shell. It is of much larger dimension than is usual for this type of boiler, and lined with firebrick over a layer of insulating brick. Over the top of the flue ends are built two brick arches extending well into the combustion chamber which give a maximum length of travel to the flame. This ensures that combustion is completed before the gases enter the tubes, and thereby avoids the flames licking into and overheating the ends of the tubes.

These arches have the additional effect of causing an abrupt change in direction in the flow of the gases which results in a large proportion of the light ash carried over from the fire being deposited at the back of the combustion chamber, whence it can be removed at intervals.

Induced Draught.

(1) Fuel can be burnt at a much higher rate per square foot of grate than is possible under natural draught conditions, enabling larger outputs to be obtained.

(2) Combustion conditions in the flues and combustion chamber can be rapidly adjusted to ensure proper combustion and to suit varying loads.

(3) The cost of a tall chimney and its foundations is saved.

COCHRAN 'SINUFLO' WASTE HEAT BOILERS.

(Kirke Patents.)

Fig. 4 shows a boiler of the horizontal type. The design, consequent upon the adoption of the 'Sinuflo' tube, is based on consideration of the fact that gases passing through straight tubes are not directed towards the tube walls at all. Molecules flowing in a parallel direction to the tube walls pass their heat to one another until the tube wall is reached, most of the molecules themselves never reaching the wall at all. After two years' intensive experiments, numbering several hundred, it was discovered that the heat transmission could be accelerated in fire tubes

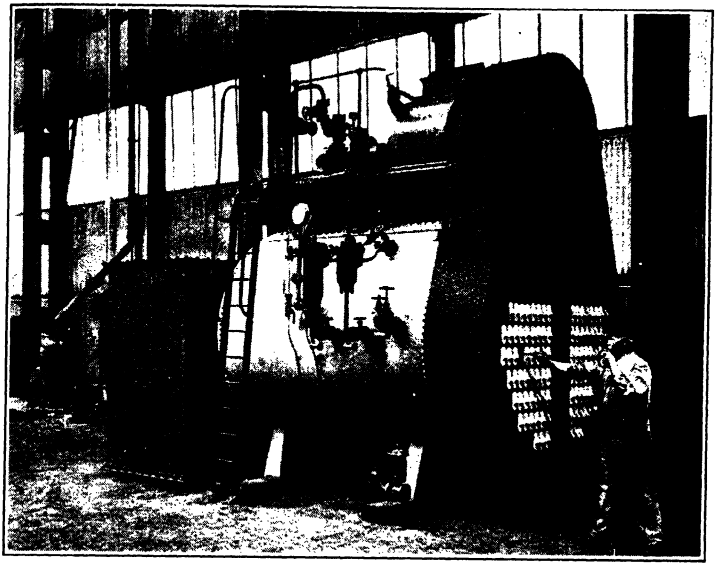

FIG. 4.

150 per cent. per unit of heating surface by so shaping the tubes without reducing their cross-sectional area that the gases were repeatedly directed towards the tube walls. Thus it became possible to reduce the tube length 60 per cent.

The frictional resistance to the flow of gases through a 'Sinuflo' tube is no more than through an equivalent straight tube.

Advantage has been taken of this discovery to increase the size of the tubes to 2 in. O.D. as compared with 1¾ in. O.D. previously popularised, thereby reducing the number of tubes to be

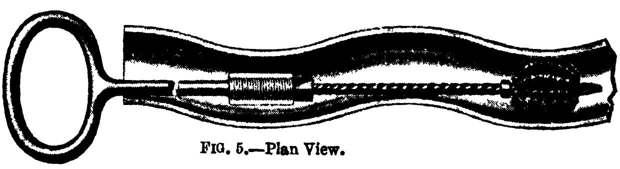

FIG. 5.—Plan View.

FIG. 6.

brushed by 26 per cent. for the same flue area. Again, the length of the tubes has been also halved and the labour of brushing more than halved.

The tubes are made very slightly sinuous, a large clear axial space (fig. 6) being left through the tube to accommodate a straight steel rod to which a spherical brush may be fixed.

Flexibility is not required between the brush handle and the brush, because the spherical brush can freely follow the waved axis of the tube.

The clear axial space between adjacent tubes is increased by 43 per cent., which renders cleaning on the water side much more easy than before.

Owing to the increased diameter of the tubes and their greatly reduced length, there is no tendency for them to sag.

The length of the clearance space for removal and replacing tubes is, of course, only half that required for the older type of boiler.

The waves in the tubes are arranged in a horizontal plane, so that the bottom of the tubes appears straight when viewed from the side, as shown in fig. 7. This prevents moisture from settling in the tubes.

The boiler in fig. 4 is suitable for working in conjunction with vertical carbonising plants, horizontal carbonising plants, water gas plants, soaking pits, and reheating furnaces and also for generating steam from the combustion of blast furnace gas in the inlet products chamber. The boilers are generally of diameter 6 ft. to 8 ft. and of length 9 ft. 6 in., the boiler shell being made in one strake. The tubes fitted are of 2-in. outside diameter and the evaporations range from about 4,000 lb. per hour to 8,000 lb. per hour. The steam raised is usually about 3 to 4 lb. per lb. of coke to producers and occasionally as much as 5 lb. when the temperature of the waste gases is high.

FIG. 7.

While retaining every one of the good points of other induced draught fire tube waste heat boilers, the following advantages are claimed for the Cochran-Kirke Patent 'Sinuflo' boiler :—

1. It occupies little more than half the floor space.

2. Only about half the space is required at the back of the boiler for withdrawing or brushing tubes.

3. The boiler may be made either vertical or horizontal.

4. The shell can be made in one ring instead of three.

5. The weight to be supported including water is reduced by about half.

6. The time required to brush the tubes is halved.

7. The heating surface is much reduced and the labour of cleaning it on the water side correspondingly saved.

8. The use of 2-in. tubes reduces the number to be brushed by 26 per cent. as compared with 1¾-in. tubes for the same total flue area.

9. The minimum space between the tubes is 1¼ in. or 43 per cent. more than with the usual 1¾ in. tubes, which renders cleaning on the water side much easier.

10. The difference of expansion on starting up between the tubes and the shell is halved which renders any form of leakage due to this cause almost impossible.

11. The tubes do not sag appreciably in the middle when the boiler is empty.

12. Owing to the length of the boiler being approximately halved, for the same evaporation, the rate of circulation in the boiler is correspondingly increased. This greatly facilitates the separation of steam from the water, ensuring very dry steam at high overloads as has been so definitely proved in water tube boiler practice.

13. The resistance through the boiler is considerably less for the same flue area owing to the substantially reduced frictional surface over which the gases pass.

For open hearth steel furnaces larger boilers are used, these ranging from 9 ft. to 13ft. in diameter with a length of 15 ft. 6 in. and with tubes of 2½-in. or 2¼-in. outside diameter. The

evaporation is from 10,000 to 18,000 lb. per hour. An average figure per ton of steel melted is 1,400 lb. Fig. 8 shows one of these boilers of 13 ft. diameter.

The initial cost of installing such boilers is generally recovered within the first year or so. The running costs are practically limited to the electric current consumed by the induced draught fan. A typical figure for fan power required is 43 kilowatts for a boiler of 12 ft. 3 in. diameter working in conjunction with a melting furnace of 90 tons capacity.

The fan power varies almost directly as the cube of the velocity of the gases through the boiler tubes, and for this reason high velocities are to be deprecated. For example, if a boiler of 11 ft. 6 in. diameter were substituted for the 12 ft. 3 in. boiler mentioned above, the fan power would be increased to 54 kilowatts and the cost of running the boiler would rise by about 25 per cent.

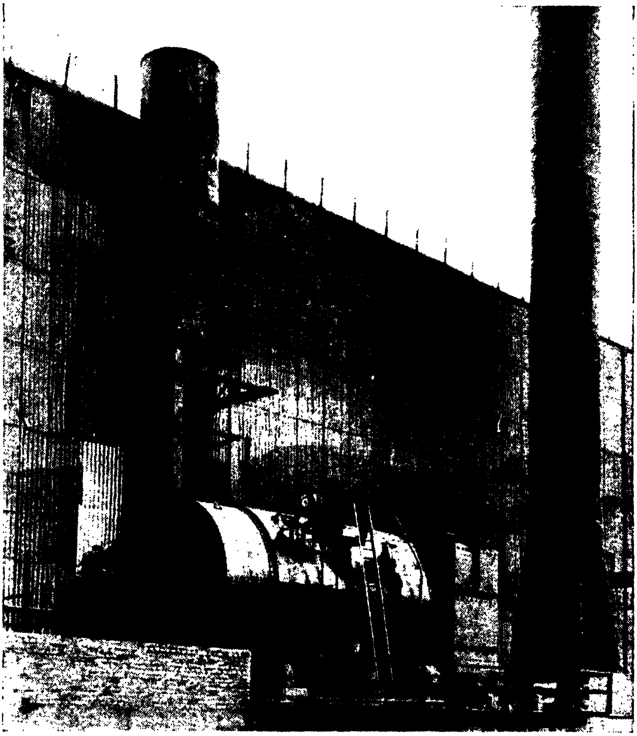

FIG. 8.—A Cochran Sinuflo Waste Heat Boiler at a Steelworks.

VERTICAL WASTE HEAT BOILERS.

For high temperature gases and where the duty is comparatively light the Cochran Vertical Boiler is adapted for use as a waste heat boiler. To obtain high tube efficiency, Sinuflo tubes are fitted, these being arranged in two nests through which the gases pass in series.

The arrangement effects a considerable saving in floor space as the boiler furnace forms the inlet products chamber and the area occupied by the boiler itself is small. So also is the space required for the brushing and replacement of tubes.

Evaporations of the order 500 lb. per hour to 5,000 lb. per hour are obtained and where fluctuations in heat input, or in steam demand, are liable to occur a steam storage effect is obtained by building the boiler with an extended top belt. The induced draught fan can be mounted on the boiler crown or at ground level.

COCHRAN 'SINUFLO' GAS-FIRED BOILERS.

(Kirke Patents.)

Fig. 9 shows a Cochran 'Sinuflo' vertical gas-fired boiler for working with natural draught, suitable for burning town's gas, water gas, clean producer gas, or sewage gas. The thermal efficiency is 85 per cent. on the net calorific value of the gas, and the following advantages are claimed :—

1. No fuel storage.
2. Minimum floor space.
3. No primary air so that back-firing is impossible.
4. Heat generated and extracted entirely within the tubes.
5. No fire-box in which explosive mixtures can collect.
6. Independent of chimney draught.
7. Complete silence due to the patent burner fitted.

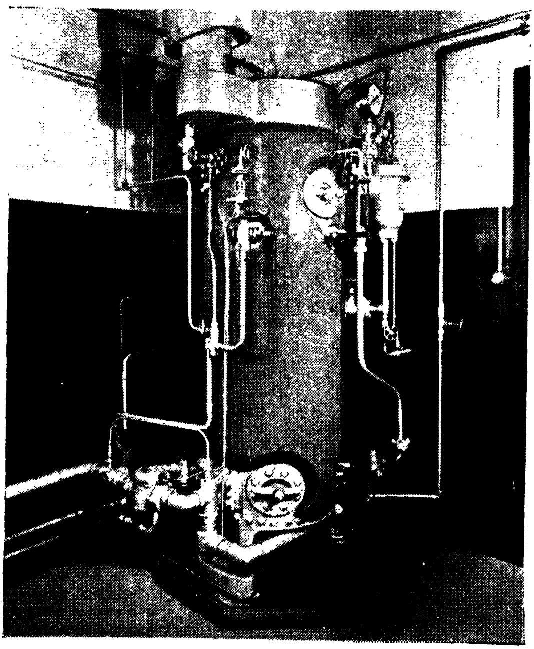

FIG. 9.

COCHRAN 'SINUFLO' EXHAUST-GAS BOILERS (KIRKE PATENTS) FOR INTERNAL COMBUSTION ENGINES.

Until recently it was customary to build Exhaust Gas Boilers of the horizontal type with straight tubes arranged either in one nest, so that the gases passed straight through the boiler, or in two nests so that the gases passed through and back again. The efficiency of the 'Sinuflo' tube has enabled these boilers with a single pass and of considerably reduced length, to be designed for the same evaporative capacities hitherto provided by the double pass of greater length. They are made in a range of sizes suitable for engines of 70 B.H.P. up to 10,000 B.H.P., and owing to the greatly reduced heating surface required, the resistance to flow of the gases through the tubes is less than that through an ordinary boiler for the same output. They are built of either the vertical or horizontal type and are economical in capital cost.

THERMAL STORAGE.

(Ruths Accumulators (Cochran) Ltd.)

One of the problems with which the engineer in charge of a boiler house is often confronted is how to cope with fluctuations in the demand for steam. The fluctuations may be irregular and violent but of short duration; regular extensive and of long duration; or of some intermediate type. The usual means available to the boiler attendant for meeting them are:

(*a*) To allow the boiler pressure to fall and to build it up again by degrees until the safety valves lift.

(*b*) To shut off the feed so that steam is raised from water already present in the boilers at saturation temperature.

(*c*) To increase the rate of firing or otherwise by attention to the fire.

(*d*) To prevail on the steam users to stagger their peak demands.

It is obvious that the efficacy of method (*a*) is largely dependent on the water content of the boilers, and that of method (*b*) on the extent to which the water level can be varied without prejudice to the safe working of the boiler.

Boilers of the same evaporative capacity but of different types may vary very considerably in their water content and in their ability to allow of water level variations, but obviously boilers with large water contents take longer to raise steam and the boilers in which the water level can be varied extensively are lacking in compactness. Method (*c*) results in inefficient working, high fuel consumption and loss of steam through the safety valves. The real solution to the problem is to provide thermal storage in a separate vessel.

Variable Pressure Accumulators—The Ruths System.

In its usual form the Variable Pressure System comprises a battery of high pressure boilers, a steam accumulator, a group of high pressure steam consumers, a group of low pressure steam consumers and a system of automatically controlled steam valves. The high pressure consumers may be power generating plant, pumps, compressors, process units requiring high temperature, etc., and the low pressure consumers dye kettles, soap boiling pans, evaporators, milk pasteurising and sterilising, etc. The system is illustrated in fig. 10. The accumulator is simply a storage

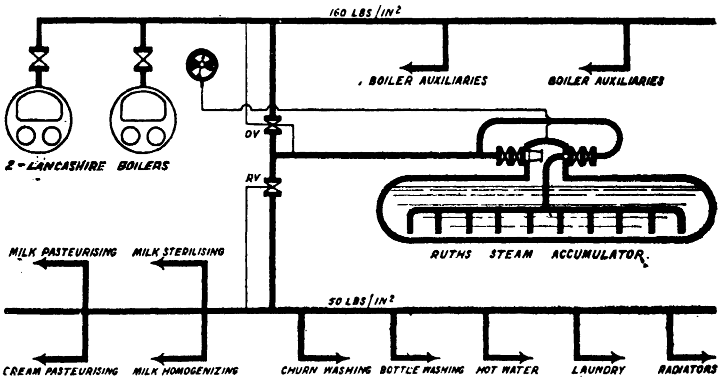

FIG. 10.—Diagram showing Interconnections and Valves between Boilers, Accumulator and Process Plant.

vessel (or several such vessels) placed *either* horizontally or vertically and generally built for a working pressure the same as that of the high pressure boiler. It is filled with water to about 90 per cent. of its capacity.

The principle is that the boilers are worked at a steady load corresponding to the total average demand from both high pressure and low pressure consumer groups, and whereas this average may vary from hour to hour or from day to day necessitating a higher or lower rate of steaming the boiler attendant has, because of the steam accumulator, ample opportunity to alter his rate of firing by a steady increase or reduction. He can, in fact, always work his boilers to give their highest thermal efficiency.

The automatic control system is such that high pressure steam is supplied direct to the high pressure consumers and the surplus steam is directed to the accumulator. Here its effect is to raise the temperature of the water and with the temperature the pressure. The heat contained in the surplus steam is thus stored in the water.

The low pressure consumer receives its steam through a reducing valve which ensures constant pressure in the low pressure main. Thus while constant pressures, with all their advantages, are maintained in the high pressure and low pressure mains, the pressure in the accumulator itself varies in accordance with the amount of heat or steam with which it is charged.

The Ruths Accumulator was developed in 1916 by Dr. Johannes Ruths, the celebrated Swedish technician, and has been used extensively throughout Europe, America and South Africa.

Constant Pressure System.

The constant pressure or feed water accumulator is represented by the Kiesselbach, the Marguerre and the Ruths Systems. The aim is to provide feed water to the boilers at or near saturation temperature, the water being heated by hot water or live steam taken from the boilers at such times as the demand for steam by consumers is less than the boiler output. An obvious effect of the use of feed water at high temperature is to raise the evaporative capacity of the boilers enabling them, up to a point, to meet peak loads without loss of pressure.

Applications of Accumulators.

Steam accumulators are largely used in conjunction with waste heat boilers in which the heat input, and therefore the amount of steam raised, fluctuates in an uncontrollable manner.

They are also used in many industries in which the low pressure consumers are dependent for efficient operation on a constant supply of steam at constant pressure, *e.g.* laundries, textile works, iron and steel works, mines and collieries, gas-works, sugar factories, breweries, soap and candle works, chemical and allied trades, rubber and cable works, hotels, food factories and dairies, paper mills.

The following results showing the improvements effected in a laundry by the installation of a Ruths accumulator are typical:—

Output greatly improved, increase up to 12 per cent. in certain departments.

Output of one 160 in. callender raised from a maximum of 800 to a maximum of 1,000 sheets per hour.

Number of laundry operating hours reduced from 52 to 48 per week.

Process water temperature stabilised at 180° F. as compared with a variation from 140° to 165° F.

Average evaporative capacity of steam generating plant increased by 26 per cent.

Evaporation of boilers increased from 9·02 to 9·91 lb. of water per lb. of coal consumed.

Ruths Accumulators have not been used extensively in Power Stations in this country, but some forty installations were in operation on the Continent in 1939. They included:—

Power Station.	Total Volume Cu. Ft.	Pressure Range. Lb./sq. in. Abs.	Capacity Kw. h.	Turbine Capacity. Kw.
Charlottenburg	176,000	206–22	73,000	50,000
Brussels	71,000	206–37	22,000	12,000
Copenhagen	58,000	169–21	24,300	10,000
Amsterdam	53,000	206–12	23,500	20,000
Hattingen	44,000	220–22	19,950	12,000
Gothenburg	38,800	206–37	16,000	10,000
Stockholm	7,760	350–147	2,400	20,000
Brünn	12,160	147	Feed Water Accumulator	

THE 'W' CENTRAL HEATING BOILER.

(Charles McNeil, Ltd., Scotland Street, Glasgow.)

Continuous automatically controlled stoking over periods of eighteen to thirty-six hours is obtained from this central heating boiler.

The principle employed is gravity feed from hoppers attached to the sides of the boiler. The fuel falls from these hoppers on to the sloping grate at a rate dependent on the amount of fuel which is being consumed.

By the employment of a suitable thermostatic control on the air intake the temperature of the water in the central heating system, or of the atmosphere in the premises in which the boiler is employed, can be maintained at the predetermined level without attention beyond the periodic filling of the hoppers and the removal of the ash.

Coke and anthracite are the fuels commonly used.

The boiler is of welded steel construction and of a design which has proved to give a high degree of efficiency. There is a long flue travel which, in conjunction with the interposed water tube elements, ensures a low temperature in the flue gases. The heating surfaces are arranged so that cleaning can be effected with the minimum of inconvenience.

The effective grate areas are large with the consequent advantages in economy in fuel consumption and in freedom from clinkering.

Independent technical authorities have carried out tests on these boilers in which the efficiency was 80 per cent. and it was proved that the rated duties are well within the capacities of the boilers.

A range of twenty-six standard sizes of these boilers, from 325,000 to 2,000,000 B.Th.U. per hour rating, is produced for installation in factories, offices, hotels, institutions, stores, etc. For smaller buildings boilers working on the same principle but of a slightly modified design are produced in a range of eleven standard sizes from 50,000 to 300,000 B.Th.U. per hour rating.

All these boilers can be used in the high temperature water and the low pressure steam system of heating as well as in the more usual hot water system.

THE YARROW LAND BOILER.

(Yarrow & Co., Ltd., Scotstoun, Glasgow, W.4.)

This boiler, fig. 1 (p. 1218), consists of three or more drums, including a saturated steam drum of large capacity, which is connected to each of the water-drums by straight tubes. The drums are of circular section, built up of pressed steel parts, the shell generally being in one ring, so that no intermediate circumferential joint is required. The drum ends are of partial spherical form, and no stays are necessary. For higher pressures, as in the case of Yarrow boilers adopted in many recent installations, the drums are made from hollow forgings, either entirely seamless, or with riveted joints only where separate ends are attached. The tubes in both the superheater and the boiler are expanded into thickened tube plates and bell-mouthed at their ends. The tube plates on the inside of the drums are, where necessary, recessed out in way of the tube holes, to enable the expanding of the tubes to be perfectly carried out. The Yarrow boiler is supported by the steam drum, which leaves the tubes and water-drums perfectly free to expand independently.

As one of the water-drums is placed at the front of the furnace and another at the back of the furnace, the tubes joining these drums to the steam-drum are adjacent to the furnace. It is well known that, owing to direct radiation, by far the greater part of the heat utilised in a boiler is transferred in the tubes nearest the fire. From the above it will be realised that as so large a proportion of the heating surface is adjacent to the fire, the total heating surface of the Yarrow boiler for the same output and efficiency can be considerably less than is usual.

Fig. 1 indicates a Yarrow type of S.F. 3 boiler, in which the gases traverse the outer nest of tubes three times, the area of the gas passage being designed for the required velocity of gases and to provide for a good transfer of heat by convection. This type is adopted wherever possible when high efficiency is required, as it takes full advantage of the transfer of heat both by radiation and convection.

Yarrow boilers are now made in various types, the principal eight of which, with their designations, are shown in fig. 2 (p. 1219).

Another characteristic of the Yarrow boiler is the very rapid circulation through the tubes owing to their being straight and nearly vertical.

An outstanding feature of this boiler is the complete absence of any form of horizontal baffle or obstruction in the path of the gases where dirt could collect. This feature can be readily seen from fig. 1, which shows the cross section of a Yarrow boiler with superheater as arranged when the fine gases are discharged overhead at the back of the boiler.

The Yarrow type of superheater consists of one or more mild steel drums into which inverted U-tubes are expanded. Suitable internal divisions are fitted in the drum so that the required number of passes through the U-tubes can be obtained. This form of superheater is self-draining.

In order to clean the interior of the boiler it is only necessary to remove the manhole door from each drum end (each is secured by two bolts). A man has ample room in the saturated steam drum for operating the tools for cleaning the inside of the tubes. For cleaning the outside of the tubes where this cannot be conveniently done from the furnace, access doors are provided in the side and end casings.

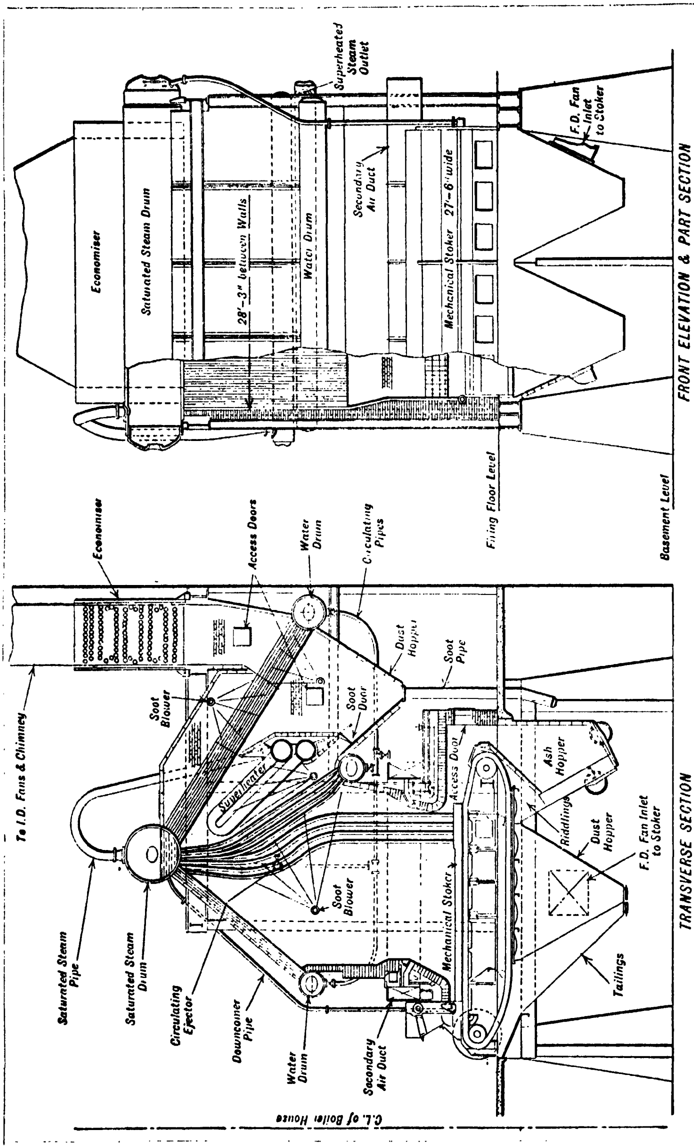

FIG. 1.—The Yarrow Land Boiler.

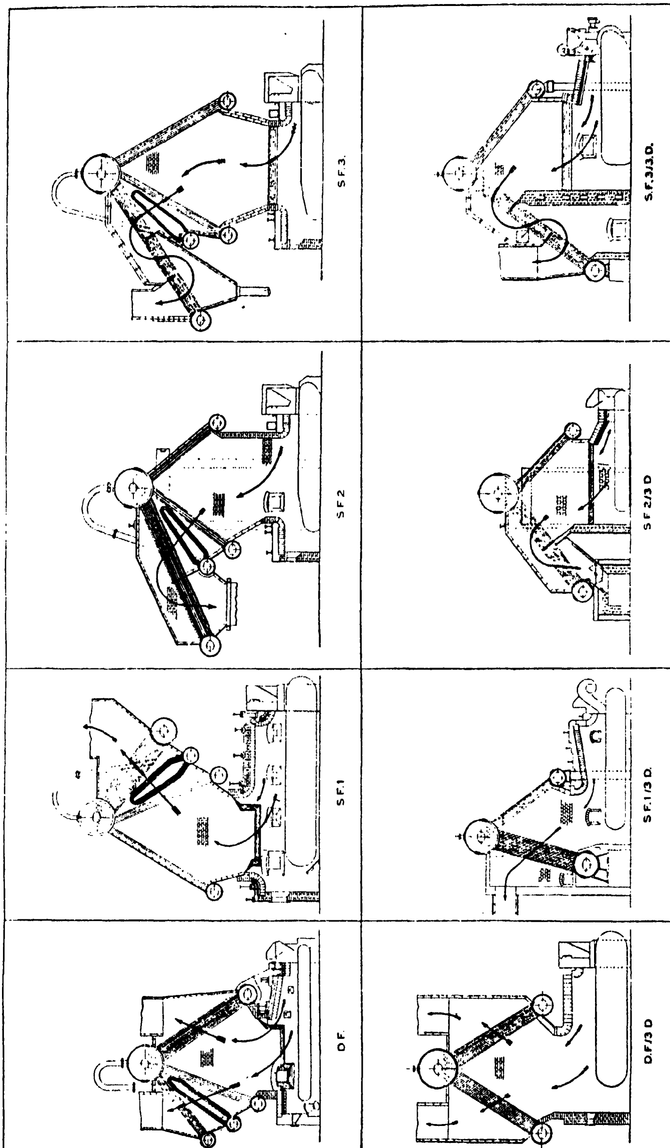

FIG. 2.—Various types of Yarrow Boilers. (Arrows indicate Gas Path.)

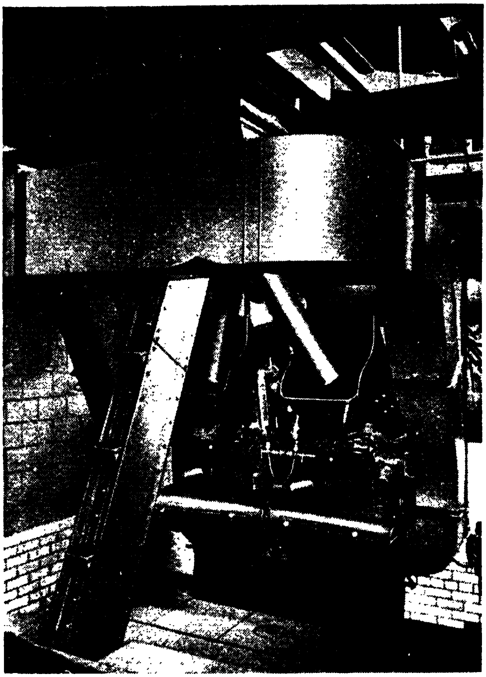
Owing to the great height of the furnace and to the large area between the tubes in the furnace rows, or, in other words, the low velocity of gases passing out of the furnace, the Yarrow boiler is found to remain comparatively clean after long periods of steaming. This, coupled with the fact that there are no places on which dirt can lodge, causes the efficiency of the boiler to be maintained.

For electric power stations where peak loads have to be provided for, the Yarrow boiler is particularly suitable, as it cannot be damaged by too quickly increasing the rate of evaporation, and it can be heavily forced without fear of damage. It is often fitted with feed-water economisers or airheaters, or with both.

Stokers.

'Bennis' Air-Draught Stoker and Self-Cleaning Furnace.

(Bennis Combustion Ltd., Little Hulton, Bolton.)



'Bennis' Air-Draught Stoker working in conjunction with 'Bennis' Automatic Elevator.

Front Plate.—The fuel feed and furnace actuating mechanisms, together with their associated driving units, are assembled on and secured to a baseplate designed to resist the warping effects of heat transmitted from the furnaces. The plate is secured to the boiler front, near to and enveloping the ends of the flues, and is extended on one side or the other, as conditions necessitate, to accommodate the gearbox units which are driven by either lineshaft-belt, motor-vee belt, or direct motor drive through flexible coupling.

The furnace driving or camshaft is connected to its gear unit by a semi-flexible large diameter coupling of substantial design, which excludes springs and rubber bushes. This shaft is fitted with a series of chilled cast-iron cams, upon whose rotation the reciprocating furnace bar motion depends. The camshaft bearings are of ample proportions, and are made integral with the side pedestals which support the front end of the furnace, together with the front deadplates and apron sheets. Altogether, these assemble into a rigid box-like formation.

Trough Bars.—The grate itself is composed of a number of interlocking grid bars manufactured from a special heat-resisting alloy. They are set in a series of air troughs, the air spaces being arranged and graduated in a manner conducive to perfect combustion. Since each trough

provides the air for a longitudinal strip of the grate, a thin or bare patch of fuel in one portion of the grate cannot affect the air distribution to the fuel over any of the other troughs.

The self-cleaning action is effected by moving all the furnace sections forward simultaneously through a short distance, then withdrawing alternate sections at a time, resulting in the bed of fuel being carried bodily away from the front end, while during the outward movement the fuel is held stationary by mass contact with those sections not in motion.

Combustion air pressure is developed by a forced draught fan producing a high velocity air flow. The profile of the duct is so shaped as to divide the air stream and pass it in correct predetermined proportions to the fuel bed. Riddlings falling into the troughed air ducts are propelled to the rear of the section concerned, and are expelled through traps into the ash chamber by a combined air pressure and mechanical means.

Grid Bars.—These are arranged to interlock securely and easily with each other into their respective carrying troughs, starting at the rear of the furnace and terminating at the more accessible front end where the front deadplate provides the final 'lock' to the system.

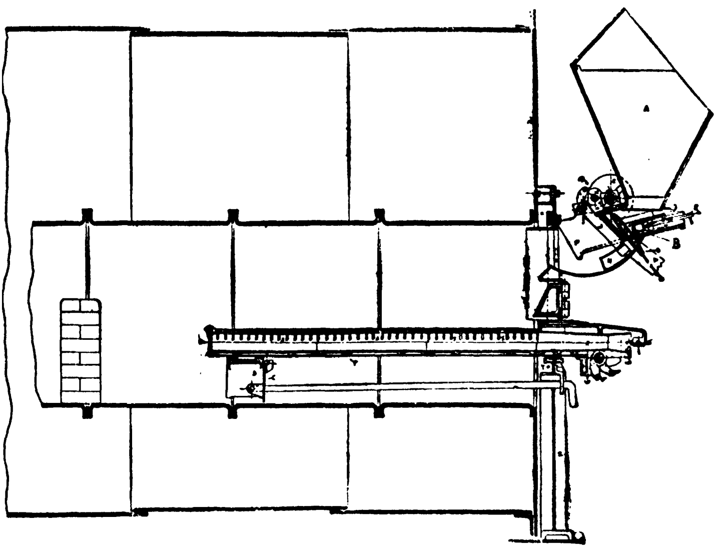
Ample space is available between the underside of the furnace components and the flue bottom for removing clinker from the ash chamber. This process does not interfere with furnace conditions, nor occasion any measurable loss in thermal efficiency.

Clinker Removal.—Clinker is removed through a chain-operated, semi-circular door by means of a specially designed shovel.

Operation.—The coal, which may be fed to the hopper by hand or mechanical means, passes to the feed-box, where the required quantity is delivered to the shovel, which then throws the fuel and spreads it over the fire in zones covering the entire grate. The fuel is slowly carried by the Self-cleaning Air-Draught Furnace to the rear end of the furnace bars; clinker and ashes are deposited in a chamber between the ends of the bars and the bridge, to be withdrawn as outlined above.

CROSTHWAITE MECHANICAL STOKER.

(*Crosthwaite Furnaces and Scriven Machine Tools Ltd., York Street Ironworks, Leeds* 9.)



Crosthwaite Mechanical Stoker and Self-cleaning Furnace.

The cheapest and smallest fuels of almost all kinds can be burned with high efficiencies with this sprinkler type of mechanical stoker. The illustration shows the application of the type to Lancashire and Cornish boilers. It works with equal efficiency on Water Tube and Sectional

Heating boilers. On the latter it is one of the very few plants that will handle all fuels from coke breeze and anthracite to high volatile coals. It is manufactured by Crosthwaite Furnaces and Scriven Machine Tools, Ltd., Leeds.

Beneath the hopper (A) there is a feeder slide (B), which has a forward and backward motion actuated by a cam. The stroke of the feeder can be regulated easily to suit the rate of feed required even whilst the stoker is running. The feeder pushes the fuel in small quantities over the edge of the feed-box (F) to the firing nose, dividing it during this process. The fuel is then thrown on to the grate by the swinging shovel (H). This shovel is carried on a central arm, which swings in a passage directly through the centre of the feed-box, and is almost noiseless in action.

The swinging shovel is actuated by a tension spring and a hardened roller working on a three-point cam. A special device permits instant release of the shovel the moment this reaches the limit of its backward stroke. This greatly reduces the spring tension, and therefore the power required to drive the stoker.

The throw of the shovel can be adjusted by means of the spring tension, and at its minimum the stoker, in conjunction with the self-cleaning furnace, becomes practically a coking type stoker.

Crosthwaite Self-cleaning Furnace.

This furnace is of the reciprocating type. The grate is divided longitudinally into close-fitting sections. Each section is a separate and complete unit carried in a mild steel channel. A set of cams push forward all the sections in unison, moving the fuel slowly towards the back of the grate. Independent cams return each section successively to its original position.

The forced draught is created by fan-driven air or by steam jets, each section having one jet.

The self-cleaning furnace is suitable for either hand firing or automatic stoking. The Crosthwaite Stoker and Self-cleaning Furnace are driven by separate gear-boxes, so that the speed of the stoker may be altered independently of the furnace.

This grate is suitable for all fuels except those of the pure anthracite type. It is especially designed to burn, with the minimum of smoke, low grade fuels from slurry upwards on boilers working under heavy loads. It gives complete combustion and the boiler load can be held fully during the periodical removal of ash.

Crosthwaite Fixed Forced Draught Furnace.

This furnace will burn efficiently the lowest grades of fuel. It maintains constant and even heat, and the upkeep costs are claimed to be very low. The firebars will last practically the lifetime of the boiler. Forced draught is created either by steam jets or by fan air. Steam consumption of the jets on the Crosthwaite furnace is not more than 2½ to 3 per cent. of the steam raised. The initial cost of steam jets is low. The initial cost of fan air is somewhat higher, but the running cost is less than that of steam jets if electric power is available at a reasonable cost. Fan air gives a quicker steaming start, a higher boiler duty and it is silent. In the Crosthwaite fan-driven air furnace, steam jets are fitted as a standby.

Sawdust, wheat chaff, bagasse, coal dust, slurry and indeed any combustible refuse can be burnt with the highest efficiencies in the Crosthwaite forced draught furnace.

Type 'L' Travelling Grate Stoker for Water-Tube Boilers.

(International Combustion Ltd., Nineteen Woburn Place, London, W.C. 1.)

This machine in its standard form is capable of burning practically any type of coal or coke, and in a modified form, wood refuse, Bagasse or similar fuels. It can be made in sizes up to 850 sq. ft. of active grate area and for steam ratings up to 400,000 lb. per hour with one stoker.

The design of the moving grate is an outstanding feature of this stoker. Referring to fig. 1 it will be seen that the grate bars are disposed transversely on the grate and lie upon each other like roof tiles. Each bar is pivoted at its ends and overbalances as it passes around the rear idler of the stoker, thus dislodging any adherent clinker or riddlings. This relative movement of adjacent links produced by pivoting neighbouring bars on different centres is claimed to be an exclusive feature, and accounts largely for the success which has attended this machine since it was first introduced in 1926.

The firebars are strung upon endless steel chains occurring at intervals across the grate and spaced correctly by tie rods of special design. The chains are equipped with rollers which take the drive from the driving sprockets and also carry the grate during its journey through the furnace.

The grate is self-cleaning, the air spaces between the bars remaining clean throughout the life of the bar. Any bar can be renewed at any position in the grate without disturbing other bars. If a bar breaks and falls out, the resulting space is filled immediately by the preceding bar.

The main tension chains are completely protected from the heat of the furnace and fuel bed. The grate as a whole is flexible, and therefore unlikely to suffer severe damage in the event of an obstruction causing the chains to mount the teeth of the driving sprockets.

The second outstanding feature of the 'L' stoker is the method of air distribution. Instead of having large, deep, air compartments connected to air supply ducts at the sides, the air is delivered to a large undivided reservoir beneath the grate and distributed by adjustable gates arranged in frames having shallow hopper-shaped depressions, immediately beneath the grate. There are several gates in each transverse row, comprising one combustion zone, all the gates in each row being operated simultaneously. This construction gives the maximum possible volume of air supply chamber beneath the distributing gates, thus reducing the chances of varying air pressure caused by velocity head and eddies.

Combustion is under perfect control, enabling widely varying fuels to be burned efficiently. The whole of the main frame of the stoker is cooled by the air for combustion, and the upper transverse members are completely protected from radiant heat by the air distribution gate frames which are substantial iron castings.

In the foregoing the 'L' stoker has been dealt with in its most widely-used form, viz. as a forced draught stoker fed with air from an external fan. It can be applied in other forms, including the self-contained type in which the forced draught fans and driving mechanism are arranged on the stoker itself and the natural draught machine, which is a simplified version of the forced draught stoker.

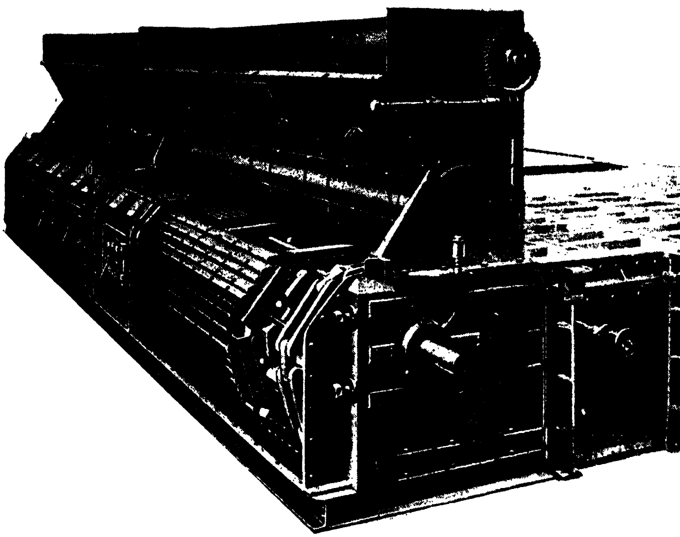


FIG. 1.—Part view of the Type 'L' Stoker, showing sections of the front removed to show the interior grate construction.

Various types of driving mechanism can be supplied to meet different cases. The most common type is the self-contained gear box giving either four or eight speeds and driven by an electric motor. In cases where automatic boiler control is to be employed, a special gear can be supplied suitable for use in conjunction with a variable speed motor. Where standby driving facilities are essential, they can be arranged by installing line shafting either above or below the firing floor, connected to the alternative driving units through the medium of clutches or fast and loose pulleys, and driving the stoker gears either through chains or vertical shafts.

The Riley Spreader Stoker.

(International Combustion Ltd., Nineteen Woburn Place, London, W.C. 1.)

The Riley Spreader stoker can be fitted to any type of water tube boiler and combines many of the advantages of pulverised fuel firing with those of a mechanical stoker, the fines being burned in suspension and the heavier particles distributed over the grate. The fuel is thrown or sprinkled over the entire grate surface by means of revolving plates forming the coal feeding units, one or more of which are mounted on the front wall of the furnace above the grate level. The fresh coal falls on top of the fuel bed and ignition is instantaneous. Forced draught is introduced under the grate and this chills the ash which is always on the underside of the fuel bed tending to reduce the formation of clinker and acting as a heat insulator to protect the grate from the high temperature of the furnace.

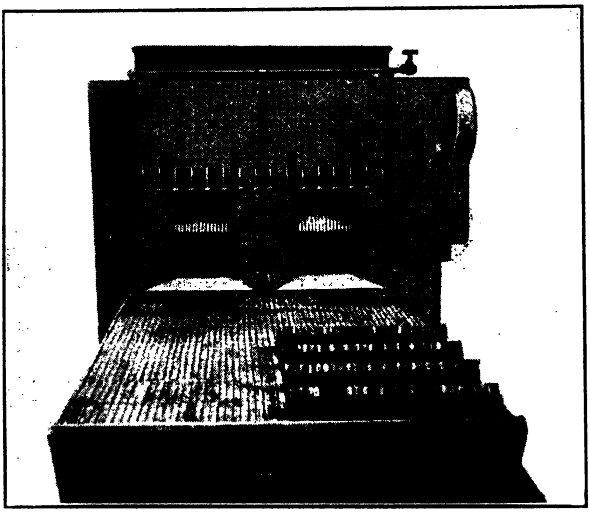

FIG. 2.—Riley Spreader Stoker.

Ashing is carried out by rocking the grate (which is divided longitudinally for this purpose), or in the travelling grate type by moving the grate to give continuous ashing either at the front or rear as may be convenient. This moving grate should not be confused with the better known travelling grate stoker which feeds the coal; on the spreader stoker the speed of the grate is regulated by the ash content and is consequently only a fraction of the rate required for coal feeding. As the fly ash and grit carry over is considerable a collecting and re-firing equipment is a normal feature of a spreader stoker installation; re-firing is carried out by means of a high pressure fan.

The spreader stoker will take any kind of rough slack coal, and thus permits of a wide choice of fuels. Coals high in ash content can be burned economically on the travelling grate to obtain the benefits of continuous ashing. The method of burning ensures a high rate of combustion and great flexibility in picking up and dropping boiler load without pressure variation. Automatic control can readily be applied, and as the power absorbed is low with either type of grate the stoker makes an attractive proposition for boiler evaporation up to say 200,000 lbs./hr.

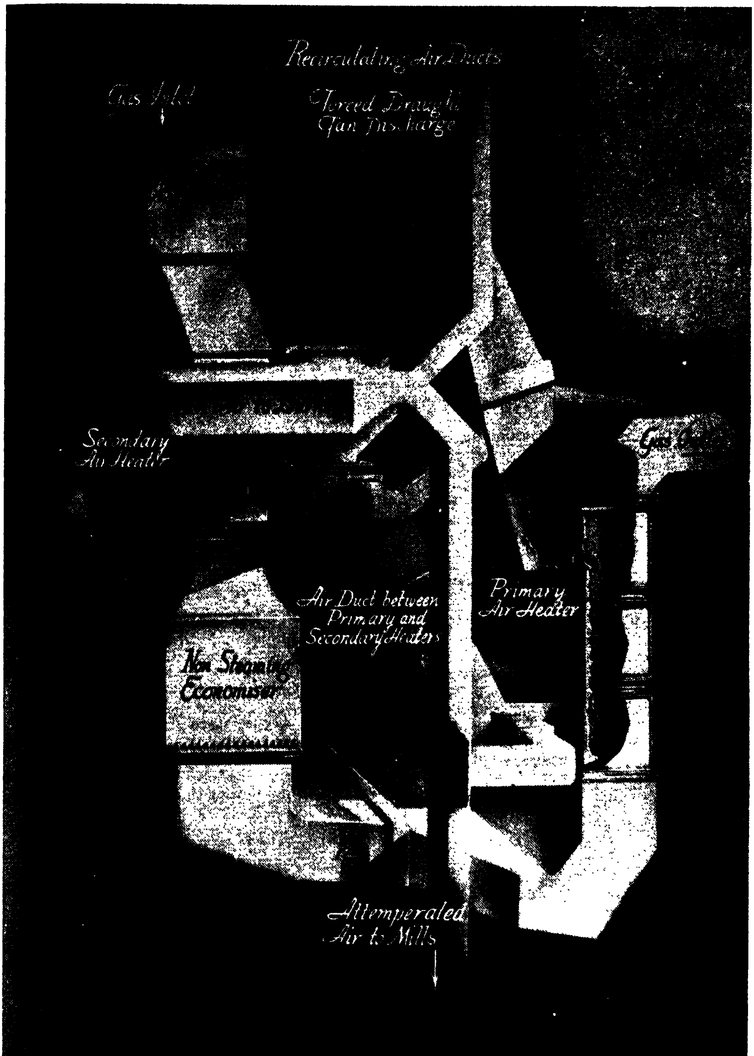

FIG. 1.—'Usco' Plate Type Air Heater.

THE 'USCO' PLATE TYPE AIR HEATER.

(International Combustion Ltd., Nineteen Woburn Place, London, W.C. 1.)

The 'Usco' plate type airheater is a high efficiency heat recovery unit providing preheated combustion air and by virtue of a special arrangement is peculiarly suited for pulverised fuel firing, where a high degree of preheat is required.

In construction, the air heater consists of a steel casing in which is contained a number of plate elements, each element comprising two plates electrically welded together to form an air- and gas-tight envelope. The edge of each envelope is pressed in such a manner that they present a perfectly streamline face to the passage of air or gas, with the result that no undue loss of energy occurs. Each envelope and the plates of the envelopes themselves are kept their uniform distance apart by means of special streamlined distance pieces, which do in effect help the passage of air through the heater.

The envelopes or elements are welded together in batches of ten, each batch being provided with a lug to permit of easy erection at site. These groups are then assembled in the casing and bolted, the casing is welded and the whole construction rendered perfectly air- and gas-tight. The 'Usco' air heater thus divides the flue gases to be cooled and the combustion air to be heated into alternate parallel streams which flow in opposite directions. The air flows through the elements or envelopes and the gases through the spaces between the adjacent elements. It will be noticed that the gas flow takes a straight path, whereas the air flow changes in direction both at inlet and outlet. The air and gases are made to flow in counter current directions in order to maintain a maximum and more or less constant temperature difference.

Plate temperature is an important factor in the operation of any type of plate heater, since the temperature must be sufficiently high to avoid condensation of the moisture present in the flue gases which causes choking of the gas passages and ultimately, by combination of the moisture with the oxides of sulphur contained in the products of combustion, corrosion of the heating surface by sulphuric acid attack. In the 'Usco' heater arrangements are made for a suitable proportion of the air to be recirculated so that the element metal temperature is maintained at the optimum figure under normal conditions of operation.

Plate heaters are usually disposed to suit vertical gas flow, the air being introduced at the sides of heater in a variety of arrangements. As applied to water tube boilers the heater is carried on an extension of the boiler structure or on the fan floor structure if the heater is above the boiler unit. For stoker fired boilers taking combustion air up to 300°F. a single heater is usual in series with the economiser if such be fitted. For pulverised fuel firing where air temperatures in excess of 500°F. are usual, it is necessary to arrange two heaters in series with provision for attemperated air supply to the mill. A typical layout is shown in fig. 1; the secondary air heater is located between two sections of economiser so that the gas flow is, in sequence, through steaming economiser, secondary air heater, non-steaming economiser, primary air heater to gas outlet. The air circuit is from the forced draught fan discharge through the primary air heater; thence by interconnecting ducting to the secondary heater with outlet to burners. Attemperated air to mills is taken from both primary and secondary heater outlets; there is an air byepass on the primary heater, while the recirculating ducts enable the F.D. fans to draw a percentage of heated air from the interconnecting duct for recirculation through the primary heater. Control of recirculation, attemperated air, etc., is by means of remote controlled dampers. Such an arrangement provides in an efficient way for the requirements of the pulverised fuel equipment and is, despite the apparent complication, simple in operation and maintenance.

Soot blowers are not now fitted to 'Usco' air heaters, as they merely increase the liability to corrosion by the introduction of additional moisture without presenting any advantages in maintaining cleanliness. In fact recent investigation into the source of bonded deposits has shown that soot does in many cases aggravate such deposits in that the dust cakes. Ample and well disposed cleaning doors for use during periods of overhaul have been found much more useful.

THE 'ROBOT' AUTOMATIC STOKER.

(Riley Stoker Co. Ltd., Nineteen Woburn Place, London, W.C. 1.)

The Riley 'Robot' Automatic Stoker (fig. 1) is of the underfeed type, designed to give smokeless combustion when burning bituminous and semi-bituminous coals. It is arranged for fully automatic control by thermostats or pressurestats, and other forms of control, such as time switches, can also be used. The stoker is of British design and construction throughout, being manufactured at the Derby Works of the Company's associates, International Combustion Limited.

The stoker consists generally of a coal hopper, worm conveyor, stoker body and firepot, variable speed gearbox, forced draught fan, electric driving motor and automatic controls. It can also be arranged to feed direct from the coal store to the boiler, in which case the coal hopper is not supplied.

The stoker body is of heavy cast iron construction and is made in two parts for easy assembly. The air duct and air chamber are formed within these castings, so that no brickwork is required for the construction of the air chamber. The firepot castings are in segments which fit into a grooved holder casting, and thus any segment can be replaced without the necessity of renewing the whole firepot.

On machines above the No. 1 size, a surrounding grate of firebars is fitted where possible. This grate assists in the final combustion of the fuel and enables the fine ashes to be riddled through the fire bars into the ash pit below. A feature of the surrounding grate is that the fire can be maintained by hand stoking in the event of failure of the electric supply.

The driving gear is enclosed in a dust-tight cast iron case and is designed for silent running. A small pump ensures positive lubrication to all moving parts. A safety clutch is provided, which prevents damage to the gearing in the event of tramp iron, or other hard substances, being in the coal.

Feed variation is effected by varying the number of ratchet teeth engaged by the driving pawl. When automatic controls are fitted, a small pulling motor is mounted behind the gearbox and this automatically puts the stoker on to the required feed, at the same time adjusting an air damper to suit. Thus the amount of air supply is automatically maintained in correct proportion

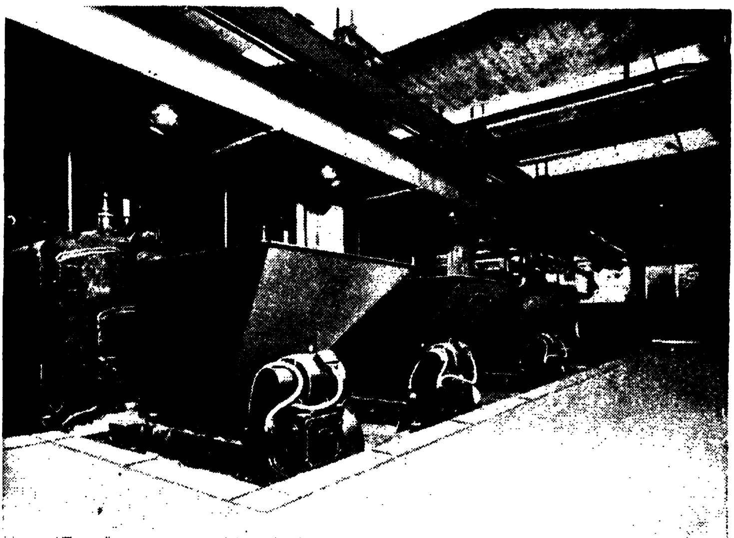

FIG. 1.—' Robot ' Automatic Stoker.

to the amount of fuel fed to the furnace. The pulling motor is influenced by a main controlling thermostat, or pressurestat, which is fitted to the boiler and a second thermostat is provided to act as a limiting device, should the temperature continue to rise when the stoker is on low feed. A special control box is provided for the electric driving motor, complete with master switch, fuses, overloads, relay and terminals suitably wired for the automatic controls.

The Riley ' Robot ' Stoker is suitable for firing all types of sectional, vertical and locomotive boilers and is also used extensively for firing core stoves, forge and annealing furnaces, brick kilns, dryers, air heaters, oil heaters, etc. It is made in several sizes to burn from 12 to 1,000 lb. of coal per hour.

THE CLASS ' B ' STOKER FOR FLUE TYPE BOILERS.

(*Riley Stoker Co., Ltd., Nineteen Woburn Place, London, W.C.* 1.)

The Class ' B ' Stoker is similar in principle to the ' Robot ' Automatic Stoker described above, and it has been specially designed for boilers of the Lancashire, Cornish and Economic types. The stoker has single centre retort with terraced grates on either side, and the air chamber is formed by a curved plate, to suit the circular flues of these types of boilers. Combustion space is limited in these circular flues but smokeless combustion is achieved due to the underfeed method of firing.

The Stoker consists of a coal hopper, worm conveyor, retort and grate, air box, air chamber and furnace front fitted with fire doors. It is a forced draught stoker, and is supplied either with a self-contained dust-tight gearbox, forced draught fan and electric driving motor, or with a ratchet

gear which can be driven from overhead shafting. With the latter arrangement, the air is supplied from a separate forced draught fan through underground or overhead ducting.

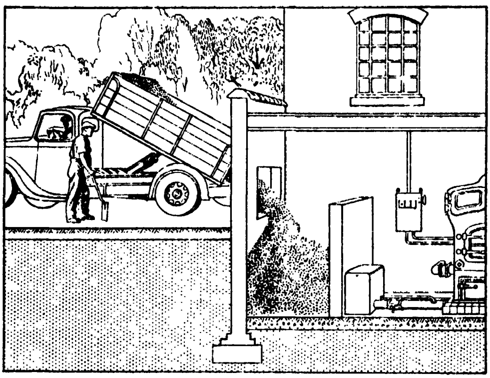
The Class ' B ' Self-contained Stoker can be auomatically controlled by thermostats or pressurestats. The controls are similar to those described above for the ' Robot ' Automatic Stoker.

The 'Iron Fireman' Stoker.

(Ashwell & Nesbit, Ltd., Barkby Road, Leicester.)

The disadvantages of using coal as a fuel in relatively small plants have been successfully overcome during recent years by automatic stokers. A prominent example is the ' Iron Fireman,' which is manufactured by Ashwell & Nesbit, Ltd.

This stoker is specially designed to ensure complete combustion, and this feature, in conjunction with the automatic controls supplied, effects a considerable saving in fuel costs; as much as up to 50 per cent. has, it is claimed, been saved over hand-firing, and up to 75 per cent. over oil-firing. In addition there is a large reduction in labour charges as only one hour or less per day of 24 hours is required for attention.



The bunker-to-boiler type stoker illustrated is the latest design to eliminate handling of coal. The coal is delivered to the bunker by the coal merchant and is not handled by the boiler attendant at all. In this type of machine the drive unit is located between the coal store and the boiler and the length from the face of the coal store to the front of the boiler could be any increment from 5 ft. to 20 ft.

This machine is made in many sizes from 200,000 B.T.U's. per hour to 10,000,000 B.T.U's. per hour.

The machine burns coal of the ' pea ' or ' bean ' size, which can be obtained at a much lower cost than either coke or normal steam coals. The standard bituminous machine is made in 14 sizes from 100,000 to 10,000,000 B.Th.U.'s per hour.

The correct volume of air required for combustion is forced through venturi air ports under the fire by a multi-vane fan. On the suction eye of this fan is fitted an iris type damper by means of which the volume of air delivered can be very closely regulated. The worm is driven through a multi-speed oil bath gear-box by a small electric motor. This small motor also drives the fan.

The coal is conveyed from the hopper by means of a worm to a retort which is fixed inside the boiler or furnace. The top layer of coal is incandescent, and as the green coal is fed underneath the fire, the gases which are released at a comparatively low temperature must pass through the incandescent layer of fuel and are thus completely burned, ensuring perfect combustion and absence of smoke. The ash in the coal is allowed to fuse into clinker and is removed once or twice per day.

The transmission to gear-box and fan is by means of ' V ' ropes, and as the motor is mounted on an insulated base plate, the whole unit is quiet in operation.

To safeguard the mechanism various safeguards are fitted, one being a safety shear pin in the event of tramp iron being jammed in the worm. The obstruction is forced to jam at a special place where it can be easily removed and the shear pin replaced in a few moments. A thermo trip device is also located in the motor, so that in the event of the motor overheating from any cause it is stopped.

The stoker is of pressed steel construction where possible and is cellulose sprayed, the finish giving it a very pleasant appearance.

Each stoker is provided with a full set of automatic electrical controls which cut out the motor on pre-determined temperatures or pressures being reached, and start the motor again when more heat is required.

The stoker can be applied to most industrial processes which call for heat, and the makers report that it has been applied successfully to cast-iron sectional heating boilers, domestic hot water service boilers, vertical steam boilers, underfired multi-tubular boilers, core and mould stoves for foundry work, oil heating furnaces, metallurgical furnaces, bakers' ovens, greenhouse boilers, tea dryers, hot air drying stoves, brick and tile kilns.

Superheaters.

'MELESCO' SUPERHEATERS FOR WATER TUBE BOILERS.

(*The Superheater Company, Limited, London and Manchester.*)

This superheater (fig. 1, p. 1230) is suitable for any type of water tube boiler. The elements are of the multiple loop type fabricated by means of the Superheater Company's machine forging process.

For intermediate pressures and temperatures up to 850° F. the element connections to the headers are of the ball and cone metal to metal type and individual elements can therefore be detached without damage to the tubing, joint, or adjacent elements.

For high pressure and temperatures in excess of 850° F. a short section of tubing is welded to the headers during construction and individual elements welded to these short sections during the erection of the superheater on site.

No header hand-hole fittings are required with either of these 'MeLeSco' joints.

'MeLeSco' superheaters for water tube boilers are usually either of the pendant type in which the tubes are arranged in a substantially vertical manner, or the self-draining type having horizontal elements. Each arrangement possesses certain advantages and the type it is preferable to employ depends upon a number of factors, foremost among which is continuity of operation of the plant.

With high temperature superheaters every precaution must be taken when raising pressure and placing the boiler on line to prevent overheating of the superheater tubes, and in the case of intermittent service the self-draining arrangement is of advantage from this operating point of view.

The pendant superheater has the advantage that element tube distortion is minimised and the whole superheater can be carried either from the superheater headers or from external steel-work in a simple and robust manner, whereas the horizontal elements of a self-draining superheater must of necessity be supported by slings which are exposed to high temperature gases and subjected to considerable loading. The use of heat-resisting alloy steel for this purpose is therefore unavoidable, but in 'MeLeSco' superheaters of this type the amount required is reduced to a minimum by employment of steam and water cooled supports of special design.

'MELESCO' INTER-CONTROLLED SUPERHEATERS.

(*The Superheater Company, Limited, London and Manchester.*)

The 'MeLeSco' Inter-Controlled Superheater (fig. 2, p. 1231) consists of primary and secondary superheater sections having a non-contact desuperheater connected in series between them. The desuperheater comprises a number of U-shaped steam tubes submerged in water, fed from the boiler drum, the water evaporated in the desuperheater being discharged to the boiler drum. Regulation of steam temperature is affected by varying the proportion of the total steam which is passed through the desuperheater on its way from the primary to the secondary superheaters The final steam temperature, changes in which determine the action of the control valves, is measured at the outlet of the secondary superheater by a thermostat, suitable means being provided to transmit the direction and extent of these changes to mechanism which in turn control. the power medium employed for operating the valves.

The desuperheater transforms superheat into latent heat and, because it provides a means by which additional heat can be absorbed by the superheater, there is an improvement in overall efficiency which more than offsets any loss due to radiation from the desuperheater and piping connection. Such a system makes it possible to maintain constant steam temperature at the turbine stop valve regardless of variation in boiler loading and other operating conditions and affords positive protection against damage due to excessive temperature.

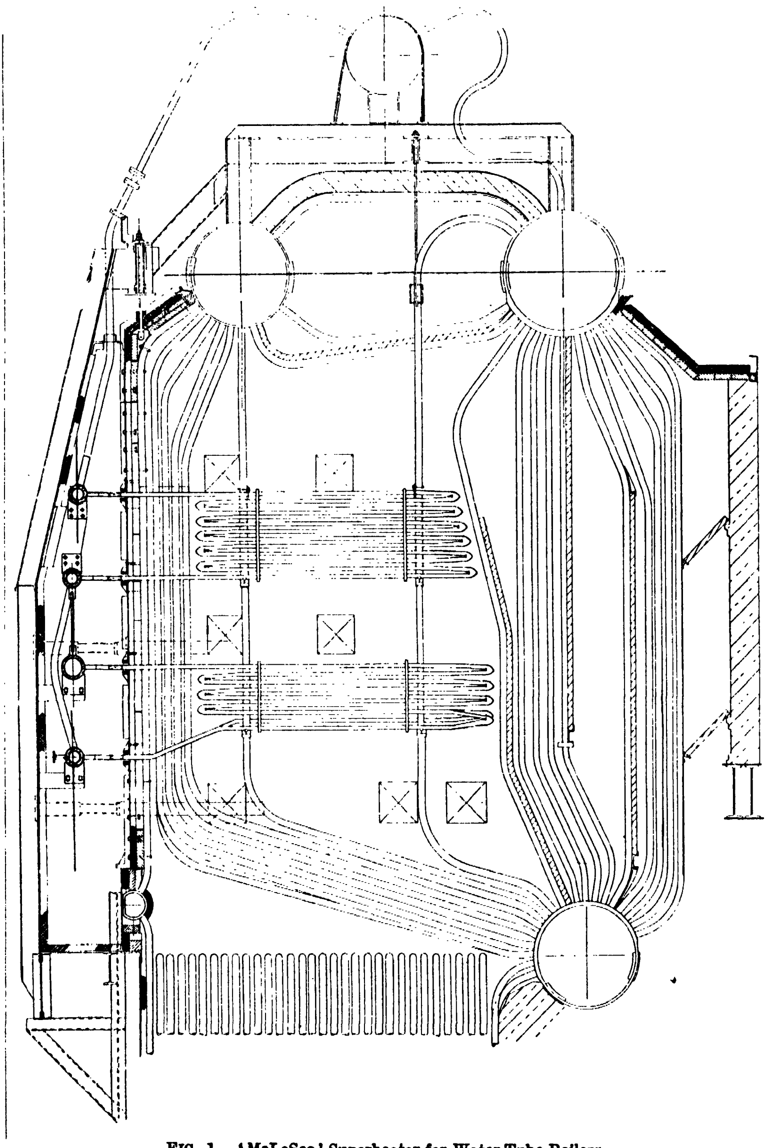


FIG. 1.—'MeLeSco' Superheater for Water Tube Boilers.

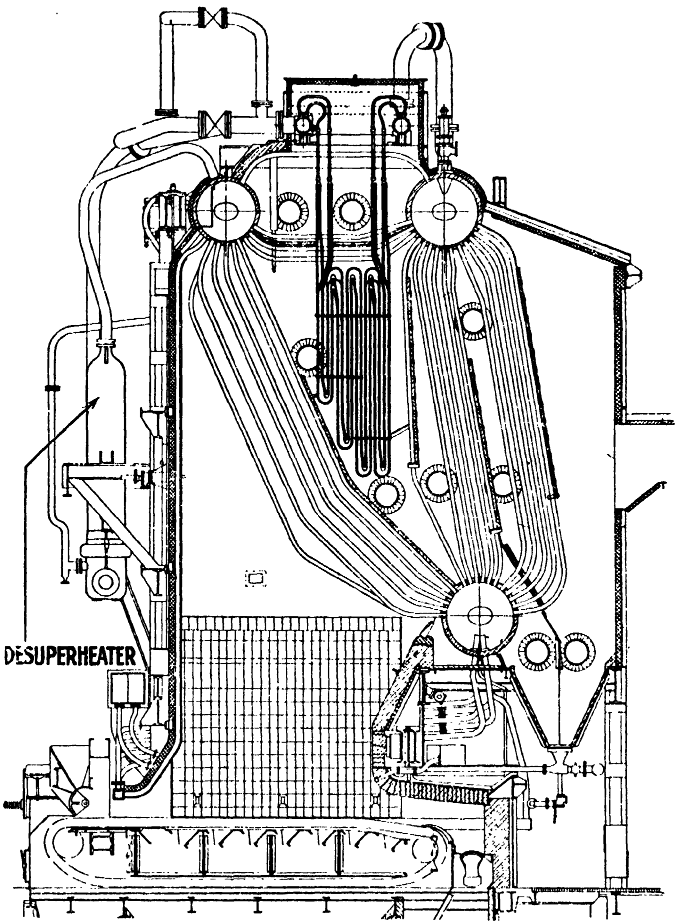

FIG. 2.—Arrangement of ' MeLeSco ' Inter-Controlled Superheater, showing Desuperheater.

Howden-Ljungstrom Air Preheater.

(*James Howden & Co., Ltd.*, 195 *Scotland Street, Glasgow, C.* 5.)

Application.—Air preheaters are installed just before the chimney in fuel combustion apparatus to recover from the flue gases any possible remaining heat before escape to atmosphere and by heating the combustion air to return this heat to the system.

As the temperature of the flue gases leaving an economiser must be 40 to 50° F. higher than the entering feed water temperature, some surplus heat is usually available in the combustion gases

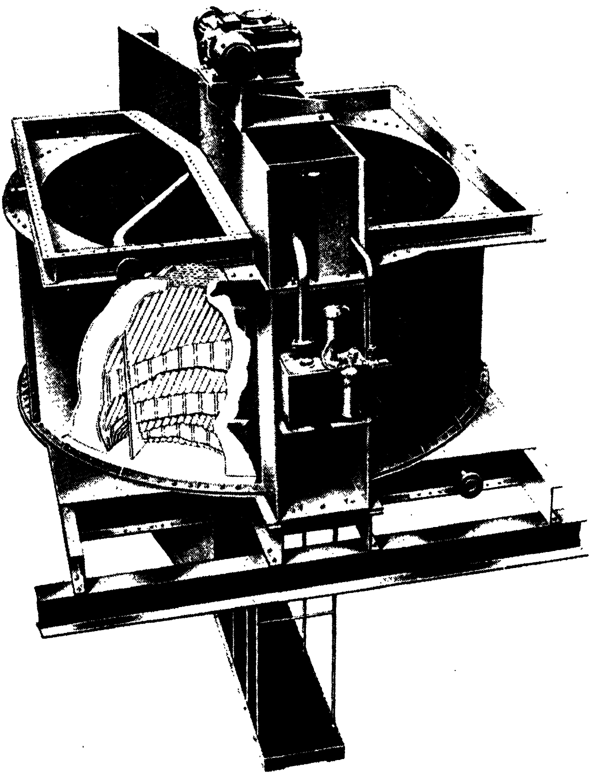

Fig. 1.

at the economiser outlet. The air preheater recovers some of this heat, thus improving the overall efficiency of the unit. Also, the use of preheated air improves combustion conditions; in fact, some low calorific value, low volatile, very high moisture or ash content fuels cannot efficiently be burned without it. With preheated air these inferior fuels are more readily ignited, leading to higher CO_2 content in the flue gases, reduced flue gas loss and thus increased boiler efficiency.

A reduction of 30 to 33° F. in flue gas temperature in the heater corresponds approximately to 1 per cent. saving in boiler efficiency. Normal gas temperature reductions in the air heater might amount to about 160° F. on stoker fired boilers and up to 450° F. with pulverised coal fired boilers, so the justification for the installation of air preheaters is evident.

Large electricity generating stations are among the largest users of preheated air.

The factor limiting the heater performance on stoker fired boilers is the maximum air temperature consistent with the avoidance of excessive renewals of stoker links.

Description.—The essential features of the Howden-Ljungstrom air preheater are the rotor containing the heating surface which forms the regenerative mass, and the casing so divided and arranged to direct flue gases axially through one side of the rotor while air for combustion passes through the other side as the rotor slowly revolves.

The rotor is an open-ended drum divided radially and concentrically into sections wherein the heating elements are carried. The heating elements are mild steel plates arranged on stoker fired boilers in packs to facilitate removal and replacement. These plates are shown in the accompanying illustrations, figs. 1 and 2. They are alternately undulated and notched, with the

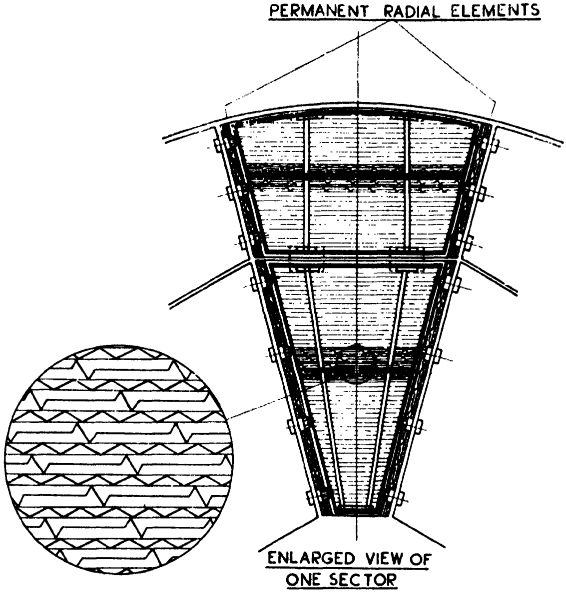

FIG. 2.

undulations running at 30° to the axis of the rotor and spaced by the notched plates which are of wider pitch and deeper than the undulations. Double turbulence of the gas flow is obtained by the sinuous passage between the undulated and notched plates in one direction and by the angle of the undulations to the direction of flow throwing the gases against the notches in the other direction.

The variation in temperature of the heating elements at any one point between the hot side and the cold side of the preheater during a complete revolution of the rotor is only a few degrees.

Howden-Ljungstrom air preheaters are fitted with a central gear drive incorporated in the main bearing housing and lubricated through an oil circulating pump with which is incorporated a filtering system, and, in special cases, an oil cooler. Both drive and bearings are designed to give at least twenty years' continuous service, and normally no replacement should be necessary during the life of the boiler.

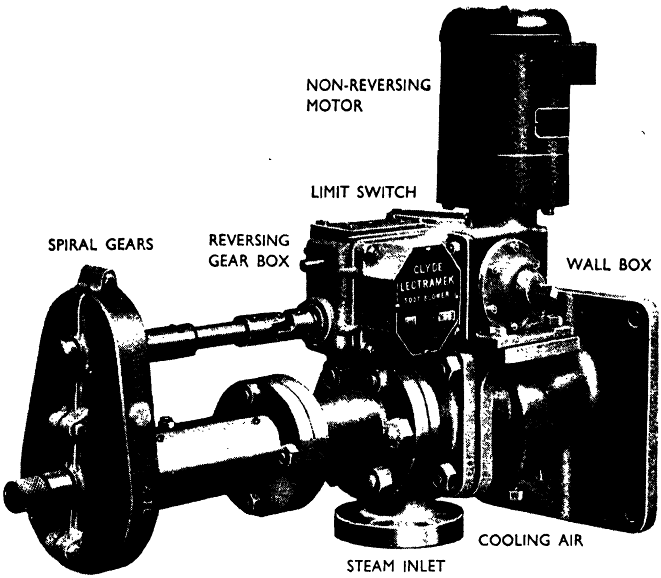
The rotor revolves slowly, ¾ to 3 r.p.m. being the usual limits of speed, and the power required to drive it is low, seldom exceeding 1 h.p. even for larger sizes. The driving motor, however, is always rated higher to provide the greater torque required at starting.

Soot-Blowers.

Clyde Soot-Blowers—Water Tube Boilers.

(*Clyde Blowers, Ltd., Livingstone Street, Clydebank.*)

The Clyde Blower, Single Nozzle Type, for water tube boilers, is built to deal effectively with the removal of slag and other deposits formed upon the furnace tube surfaces during steaming, and is designed for easy manipulation, durability in service, and accessibility in periodical examination. It is attached as a permanent fitting to the boiler walls, the nozzle being introduced into the furnace through a wallbox. A connection to the boiler provides steam, which is discharged in a powerful jet under full control of the operator. In order to spread the jet over the tube surfaces the nozzle is rocked to and fro. This is effected automatically, the motion being transmitted to the nozzle through mechanism to which the operating wheel is connected. When the blowing is completed, the nozzle is retracted and protected from overheating by a stream of cooling air introduced into the wallbox. The operating mechanism is designed for direct or remote control and an indicator is provided in close proximity to the operating hand-wheel.



Electrical operation of the Clyde Soot Blower is obtained by the application of a Lectramek Unit which is mounted on the wallbox and coupled direct to the blower mechanism. A control panel is provided for fixing at firing floor level for starting up the operating unit by push button.

The Operating Gear consists of a three-phase totally enclosed asbestos wound motor, squirrel cage non-reversing type, direct coupled to speed reducing gear driving bevel wheels mounted on a splined shaft, together with a reversing clutch automatically controlled by timing gear. The motor does not reverse but runs continuously in one direction, reversing movement being obtained by mechanical means, and is transmitted to the blower gearbox at reduced speed where it is converted to reciprocating motion.

A Limit Switch situated in the operating unit gearbox and connected to the control panel regulates the stopping and starting and the number of strokes made by the blower coming into action immediately the push button is pressed, and stopping automatically when the cycle is completed. The electo-mechanical operating gear described is applied as a self-contained unit to the blower and takes the place of the usual handwheel as fitted for manual operation.

The Control Gear consists of a dust proof steel cabinet containing all electrical contactors and fittings with an outside keyboard provided with push buttons to suit the number of blowers, each

button being protected by a cover plate with interlocking mechanism to ensure that only one blower is operated at one and the same time. The actual serial number of the blower in operation is recorded and appears through an illuminated window. Sequence control is available and is fitted in the cubicle when desired, whereby each blower functions automatically in correct rotation after being set in motion by a single start push button.

The necessary safety devices are incorporated in the cubicle together with transformer for alarm bell which comes into action in case of emergency.

Inspection Facilities.—Access to the mechanical portion of the Clyde Soot Blower is obtained as before by removing steam chest cover without breaking steam pipe joints, and it should be noted, without disconnecting electric supply wires attached to motor and limit switch. This facility is of great importance to the maintenance staff as it permits nozzle inspection or renewal to be made while the boiler is under steam. Another advantage is that the cover which contains all the working parts of the blower can be brought to the floor level where it is easily dismantled, adjustments made and replaced on the boiler in a short time.

The design of electrical operating unit has been standardised for application to retractable single nozzle blowers located on boilers in a vertical or horizontal position and to multi-jet and dual nozzle blowers as applied to economisers and air preheaters.

Clyde Soot-Blowers—Scotch Marine Boilers.

(Clyde Blowers, Ltd., Livingstone Street, Clydebank.)

Clyde blowers for application to multi-tubular boilers of the Scotch marine type are supplied for single and double-ended boilers, and are capable of operation from back or front ends. This necessitates three distinct types, classified as follows: S.M. Direct for single-ended boilers (back operated). D.F.O. Direct for double-ended boilers (front operated). R.F.M. Return flow for double-ended or single-ended boilers (front operated). Each of the above designs incorporates the usual 'Clyde' features, including self-contained steam shut off, obtained by the rotation of the blower operating wheel or handle, while both axial and oscillatory movements are also transmitted to the blower nozzle by the same wheel. A master stop valve on each boiler controls all the blowers on that boiler, and remains open whilst blowers are in use but steam is admitted to each blower nozzle in turn only when its operating wheel is used.

Standard blowers are fitted with hand-wheels or handles, for direct operation from platforms, but operating gear whereby complete control is obtained from the floorplates, is available, similar to that employed on Clyde blowers for water tube boilers. This facility enables the process of tube cleaning to be carried out without ascending ladders, or the use of platforms, and ensures that the work is effected expeditiously and with regularity. This EX type blower is applied for cleaning tubular and turbulent flow air heaters. Clyde blowers for marine type boilers and air heaters are supplied to Board of Trade requirements, suitable for superheated or saturated steam.

Clyde Soot-Blowers—Economic Boilers.

(Clyde Blowers, Ltd., Livingstone Street, Clydebank.)

The Clyde Soot Blower provides a simple method of maintaining the boiler tubes and heating surfaces free from soot without opening smoke-box doors. The time required for tube cleaning is reduced to a few minutes each day.

Another advantage is that in the process of tube cleaning with blowers, soot does not spread everywhere. The surroundings and atmosphere remain clean.

Boilers fitted with automatic stokers cannot be readily cleaned by any other method. The cost of tube cleaning by soot blowers is negligible as this is carried out by the attendant during his daily work.

Boilers can be run continuously for long periods without laying off as the tubes and heating surfaces are kept thoroughly clean by the regular use of the soot blowers. Coal consumption is thereby greatly reduced.

For a single pass economic boiler two blowers are fitted to the back of the combustion chamber, and for a double pass boiler it is necessary to fit one additional blower and in some cases two blowers at the smoke-box end. The equipment is simple to operate, and the boiler tubes can be kept consistently clean without laying off for hand cleaning, whereby considerable savings are effected both in labour and fuel.

Furnace Linings.

BIGELOW SUSPENDED WALLS FOR FURNACES.

(*Liptak Furnace Arches, Ltd.*, 68 *Victoria Street, London, S.W.* 1.)

Liptak Furnace Arches, Ltd., manufactures a complete range of unit supported fabricated walls for all types of furnace construction, ranging from very thin light weight air-cooled or insulated walls giving an insulating refractory cover of approximately 3 ins., as shown in fig. 1, to heavy duty type walls of double suspended construction either air-cooled or insulated, giving 11 ins. of refractory cover, as shown in fig. 2.

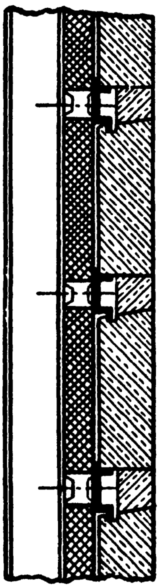


FIG. 1.

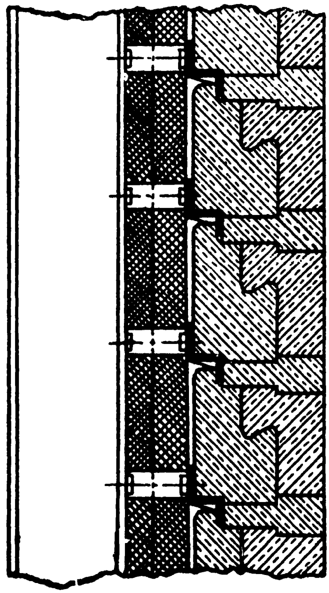

FIG. 2.

Features of these constructions exemplified in all designs within the range are that each block is independently supported and can therefore be replaced independently when necessary, and that a very much longer life is obtained from the refractory or insulating refractory material owing to the elimination of cumulative loading.

A full range of unit suspended double and single arches for boiler and industrial furnaces is also available.

Electrostatic Precipitation.

STURTEVANT ELECTROSTATIC PRECIPITATORS.

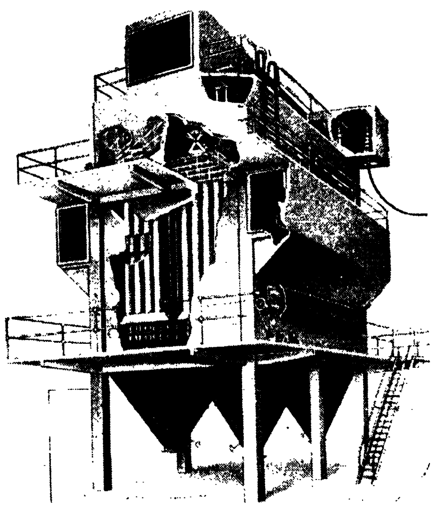
(*Sturtevant Engineering Co., Ltd., Southern House, Cannon Street, London, E.C.* 4.)

All industrial gases, as well as the atmosphere, carry solid or liquid particles which may be valuable commercially, or harmful to life and property, or of such a nature as to reduce the efficiency of some chemical process if allowed to remain in a chain of apparatus.

One of the most efficient means of removing these particles is the process of electrostatic precipitation. In this process, high voltage electricity is used to ionise the gas and its solid or liquid burden, thereby effecting the removal of the dispersoids.

The Sturtevant precipitator consists essentially of two sets of electrodes, one set charged to a high potential and termed the 'discharge electrodes,' and the other, which is earthed, called the 'receiving electrodes.' The discharge electrode system is made up of wires of suitable cross-section, and the receiving electrode system usually consists of a number of vertical tubes arranged in parallel. Each tube is equipped with a centrally suspended discharge wire and when these wires are charged to a sufficiently high potential a corona or brush discharge takes place, thus ionising the gas and dust and driving the solid or liquid particles to the receiving electrodes.

Continuous or intermittent motor-driven rapping gear is provided for relieving the two electrode systems of deposited dust which then falls into hoppers located on the underside of the precipitator casing.



The high tension equipment used by the Sturtevant Engineering Co., Ltd., is standard apparatus and gives constant and reliable operation over very long periods. The plants are so interlocked and protected that there is no danger to operators and every installation is equipped with apparatus for the prevention of interference with wireless reception.

These precipitators are used for the removal of a great variety of materials from industrial gases and the atmosphere. Powdered fuel grits, cement dust, atmospheric impurities, blast furnace dust, tar fog, pyrites dust, acid mist, crushed stone dust, lamp black, phosphate and various metallic oxides, such as those of tin, molybdenum, lead, zinc, vanadium and tungsten, as well as metallic tin, lead, zinc, nickel, gold and silver, etc., are amongst the solids and liquids collected by electrostatic plants.

In many cases large savings can be effected by the installation of an electrostatic precipitator, and even small plants, it is claimed, show a recovery of over £500 per week when used for the removal of certain metallic oxides from the flue gases in metallurgical works.

Considerable saving is also realised in acid works, which burn pyrites or blende, by the use of a precipitator located between the burners and the Glover Tower. An electrostatic plant at this point prevents the carry-over of burner dust and results in clean flues and towers, as well as clean, clear acid.

The majority of central power stations burning pulverised fuel use precipitators to eliminate the discharge of grits into the atmosphere and it is generally considered that this method is the most efficient and reliable one for doing away with the nuisance of grit emission from large stations. Most cement works are likewise equipped with electrostatic plants to clean the kiln gases before they reach the stack.

Feed Water Treatment.

THE WEIR 'OPTIMUM' DE-AERATOR.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S. 4.)

Corrosion in boilers and feed systems can best be avoided by the use of de-aerated feed water The water in an open feed system absorbs gases from the air, and becomes corrosive; the feed can be rendered non-corrosive by the use of the Weir 'Optimum' De-Aerator.

In this de-aerator the feed water is sprayed through nozzles, meeting steam from a chamber below in which the water is collected and subjected to violent ebullition by incoming steam. The rapid boiling of the water, combined with the heating action of the vapour on the spray at reduced pressure, causes the air in the water to be liberated; the air is exhausted by means of an air ejector which maintains a vacuum in the de-aerator and assists in the de-aerating action.

All the heat in the operating steam is conserved in the feed water, and the de-aerator may be conveniently included in the feed system. The amount of oxygen in the water can be reduced to entirely negligible quantities with ease. The plant gives excellent de-aeration at low as well as at high temperatures, and may be designed to operate under either pressure or vacuum conditions.

WEIR EVAPORATORS.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S. 4.)

High and low pressure evaporators (single and multiple effect) are built by G. & J. Weir Ltd., Glasgow, for both industrial and marine duty. A typical triple effect plant, comprising vertical evaporator shells with scroll type heating coil elements, is shown in the illustration (fig. 1).

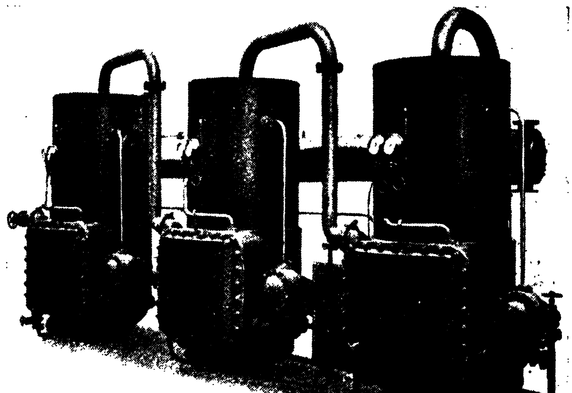


FIG. 1.—Weir Triple Effect Evaporating and Distilling Plant.

The coils are of heavy gauge, solid drawn copper, and each element may be withdrawn separately for cleaning. The water level in each shell is maintained by means of a float-operated automatic feed regulator. Special provision is made to secure freedom from priming. For marine work a brine ejector is fitted.

Fig. 2 shows a Weir horizontal low pressure evaporator, the elements consisting of straight tubes held between tube plates, large doors being fitted to allow for easy cleaning. The large water area for the release of vapour is a factor which retards any tendency to priming, and a large steam dome with baffle plates is provided.

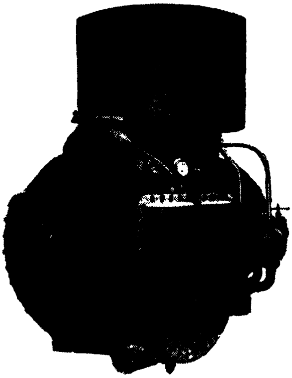

FIG. 2.—Weir Low Pressure Evaporator.

Evaporators should be installed in a power plant so as to form part of the system, the heat in the vapour produced being absorbed by suitable means so as to avoid loss. They provide an ideal means for protecting boilers, etc., from impure water, and amply repay the cost of installation. For the supply of drinking water in arid districts, plants can be operated either in conjunction with a power plant, or independently from a special boiler.

The number of stages in a multiple-effect evaporating plant depends on the steam conditions and the degree of overall economy desired, the amount of heating steam required diminishing as the number of effects increases. Two or three effects are the most usually employed in marine work, but quadruple and sextuple effect plants are frequently installed for the supply of fresh water in the tropics or in industrial works. The relative production of single and multiple-effect plants (*i.e.* the weight of distilled water produced per pound of primary steam supplied) is approximately as follows: Single effect, 0·8 to 1. Double effect, 1·5 to 1. Triple effect, 2·6 to 1. Sextuple effect, 4 to 1.

Corrosion.

BOILERINE.

(*Boilerine Ltd., Manufacturing Chemists,* 897 *Old Kent Road, London, S.E.* 15. *By appointment Manufacturing Chemists to H.M. King George VI.*)

This is a viscous fluid, consisting chiefly of a carbon compound which has no action upon iron, steel, or other metals, but which has the property of rendering all water impurities innocuous and incapable of forming scale, while it also works its way through the interstices of the scale, the rate of this percolation depending on the porosity and degree of compactness of the same, and when the preparation reaches the underlying plate of the boiler it there diffuses and insinuates itself behind the incrustation, causing it to crumble and flake, so that when the boiler is opened it can readily be removed. The preparation as a preventive of scale differs from the old style of boiler composition, inasmuch as it absorbs the gaseous carbonic anhydride from the water, forming an intermediate salt which throws the scale-forming salts out of solution, suspending them in the water in a non-crystallisable and powdery state. Incrustation is thus prevented. Steam generated from sea water containing 'Boilerine' is free from ammonia. Boilerine is not only a preventive, but also a disuniter of incrustation in boilers; it is absolutely non-volatile, and does not affect the purity of the steam produced from water treated with it; it does not discolour the water in the boiler, and it will not cause priming. It is guaranteed free from arsenic, acids, and poisonous substances, and is a neutraliser of grease and acids.

The boilers should be blown down and treated with Boilerine *daily*, as by this system greater efficiency is obtained.

BOILERINE RADIATOR CLEANSER.

If the cooling system of a motor vehicle does not receive periodical attention lime deposits form on the walls of the cylinder jackets and radiator tubes. Corrosion may also take place. There follows clogging up of the cooling system with, as a sequel, poor running, high oil consumption and increased wear.

Boilerine Radiator Cleanser has been introduced by Boilerine Ltd. to prevent these occurrences and is obtainable direct. It takes the lime into solution, is suitable for any climate, and keeps without deterioration.

ORGANIC 'ROSSELINE.'

This preparation is the ideal cleaner for domestic hot water boilers and pipes to remove the fur which causes a difficulty in readily obtaining hot water. The entire process usually takes about nine hours, the quantity requisite for this being *three* gallons. This is also a product of Boilerine Ltd.

BOILER MAINTENANCE.

(*British Paints Limited, Portland Road, Newcastle-upon-Tyne.*)

Six definite claims are made for Dampneys 'Apexior' for the internal treatment of boilers :—

(1) That corrosion from whatever cause arising will be prevented and if already rife can be checked in one application.

(2) That scale will be considerably reduced, entirely altered in character, rendered non-adherent and easily removed.

(3) That heat transmission will be appreciably increased, as certified by the National Physical Laboratory.

(4) That the process is simplicity itself.

(5) That the cost is very low, only comes once per annum at the most, and the treatment more than pays for itself.

(6) That 'Apexior' contains no chemical, does not function by means of chemical action, is non-poisonous, and is used regularly in boilers raising steam for direct contact cooking.

'Apexior' Compound easily applied once a year with a brush provides a thin but impenetrable barrier between the boiler metal and the feed water. It has been tested by the National Physical Laboratory, which found its powers of adherence unimpaired at a temperature of over 1,000° F.

Mechanical equipment is now available for the speedy and efficient coating of tubes, which can now be coated as easily as flat surfaces.

Engineers do not require to conduct periodical tests with their feed-water, or to arrange for periodical dosing of their feed tanks, as is the case with fluid remedies ; there is one operation, one cost, and the saving in labour cleaning and in renewals more than counterbalances the small expenditure. A Lancashire Boiler 30′ × 9′ can be treated for a few pounds for the initial treatment, *i.e.* two coats, and the cost is halved during subsequent years when only one coat is necessary.

More than one firm of boiler manufacturers automatically 'apexiorise' their boilers before despatching to clients in order to provide a corrosion-proof interior ; others actively recommend 'Apexior,' and its merits are well known to the majority of the principal Boiler Insurance Companies.

'Apexior' works very well in connection with water-softening plants, many of which do not deal effectively with dissolved oxygen or free carbon dioxide, two very fruitful causes of corrosion, and the whole process is so simple and reliable as to be a revelation to all who have not had the experience.

'Apexior' can also be used with marked effect in evaporators, the scale being quite non-adherent can be easily removed by a blow from a piece of hard wood, and the cleaning is carried out in a fraction of the time usually occupied.

'Apexior' has been used in boilers, economisers, condensers, calorifiers and steam turbines for thirty years, has been adopted as a standard treatment for all types of steam plant by a great number of the leading steam users—on land and sea—throughout the world, and is at present specified for the biggest boilers in the course of construction in this country.

'FOLIAC' BOILER GRAPHITE.

(*Graphite Products, Ltd., 52 Battersea Church Road, S.W. 11.*)

The use of this material enables scale in a boiler to be easily and safely removed, a wire brush being used for the purpose. The graphite does not attack the metal of the boiler, nor, it is claimed, does it cause the metal to be attacked ; it is not affected by any acid in the water or by the heat generated in the boiler. Particles of the graphite work through the minute fissures existing in the old scale and gradually penetrate between the scale and the metal. The scale thus loosened may be rapped off or removed with regular cleaning tools with little trouble. If the scale is very hard and thick it may require as long as three or four months for graphite to loosen it, but once removed the scale can never again adhere firmly to the metal as long as the graphite treatment is continued. The graphite also becomes thoroughly intermixed with new scale as it forms, rendering it soft and friable.

The graphite is introduced in the form of fine powder with the boiler feed, about half a pound being used per day for a 250-h.p. boiler.

Boiler Fittings.

Water Gauges and Cocks.

(Richard Klinger Ltd., Klingerit Works, Sidcup, Kent.)

One of the difficulties with which engineers in charge of steam plants have to contend is that of overhauling and repacking efficiently the various asbestos-packed cocks fitted as water gauge cocks, salinometer cocks, pressure gauge cocks, etc.

A type of cock known as the Klinger 'Sleeve-Packed' Cock is extremely simple to repack and, at the same time, is capable of withstanding pressures and temperatures far in excess of those possible with the old-fashioned type of packed cock. The packing takes the form of a renewable

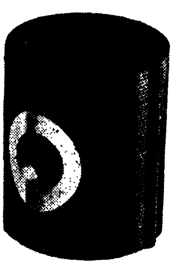

FIG. 1.

Renewable Asbestos Packing Sleeve for Klinger "Sleeve-Packed" Cock.

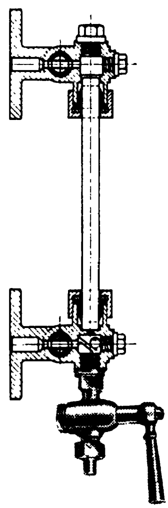

FIG. 2.

Klinger Water Level Gauge fitted with "Sleeve-Packed" Cocks.

sleeve of compressed asbestos (fig. 1), which is pushed into the body as a single unit and is compressed against the parallel plug by means of the bottom tightening nut. A ridge on one side of the sleeve fits into a groove in the body and makes it impossible for the ports to get out of line, while two stainless eyelets embodied in the sleeve around the ports protect the packing from the cutting action of the passing fluid.

Fig. 2 shows a standard pattern water gauge fitted with cocks of this type.

There is, however, a definite limit to the pressures at which it is possible to use a simple glass tube in water level indicators, and the growing use of higher and higher pressures in steam generating plant has necessitated the use of stronger types of gauges.

Fig. 3 shows the latest type of forged steel reflex water gauge made by Richard Klinger Ltd. for pressures up to 500 lb. per sq. in.

In this gauge the glass tube is replaced by a tough glass plate mounted in a forged steel body. The inside of this glass is corrugated with a number of V-shaped grooves. When steam or air is in contact with the back of the glass the grooves have a prismatic effect and light striking the glass is reflected to the eye of the observer. When, however, water rises and fills up the grooves light passes right through and is absorbed by the back of the gauge. Thus the steam space appears

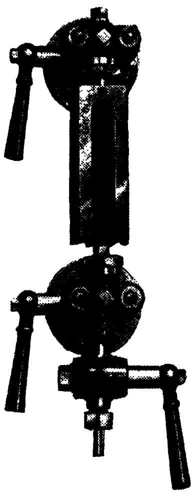

FIG. 3.
Klinger Reflex Level Gauge—
Type 'K.'

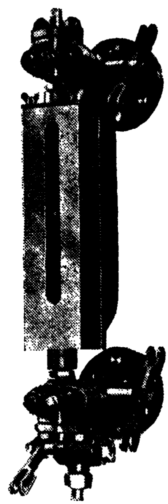

FIG. 4.
Klinger Double-Plate
Level Gauge.

bright and silvery while the water appears unmistakably black, and it is impossible for confusion to arise as to the level of water in the boiler even if it is allowed to pass out of sight in the glass.

Another difficulty encountered in modern high pressure steam plants is that of finding a glass suitable for water gauges which is capable of withstanding the corrosive action of the steam and water at such high pressures and temperatures. Contrary to what might be expected, the purer the feed water the greater is its solvent action on glass. In order to protect the glass it is, therefore, becoming usual practice to insert a thin strip of good quality mica against the face of the glass plate to keep it from contact with the steam and water.

Fig. 4 shows the latest type of mica-protected double plate gauge made by Richard Klinger Ltd. for steam pressures up to 1,200 lb. per sq. in. Two thick plates of specially toughened plate glass are bolted to either side of a steel body with the water space between them, each glass having a thin piece of mica plate against its inner face. These gauges are generally used with an illuminating device which shows up the water level as a bright spot of light. Klinger 'Sleeve-Packed' cocks are incorporated throughout, thus making a simple and reliable fitting for the highest pressures.

Regulators.

Copes Feed Water Regulator.

(Copes Regulators, Ltd., 9 Southampton Place, High Holborn, London, W.C.1.)

The Copes Feed Water Regulator consists of a thermostat, the actuating element, and a balanced valve controlling flow of the boiler feed water. A rigid strut connects the thermostat

TENSION TYPE.

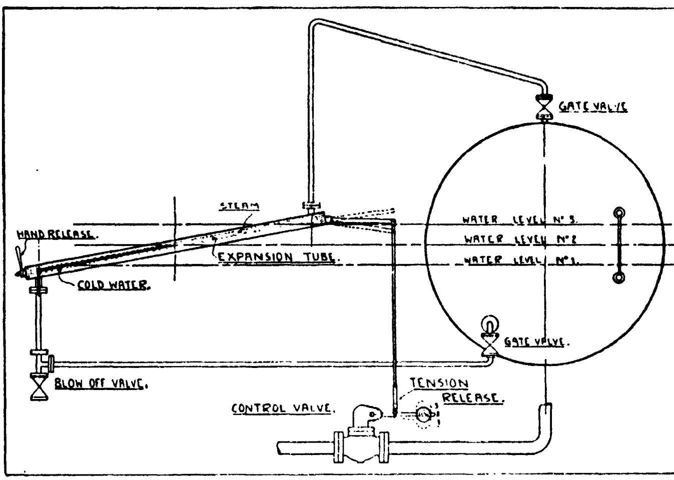

Fig. 1.

and valve. The thermostat consists of an expansion tube securely mounted between two steel channel pieces. It is so designed that the expansion tube is always in tension. The tube is welded to the flanged head and heel pieces.

The upper end of the expansion tube (see fig. 1) is connected to the steam space, and the lower end to the water space of the boiler. The same water level exists in the expansion tube as in the boiler; the upper end of the tube being filled with steam and the lower end with water. Movement of the water in either direction causes the expansion tube to act as a thermostatic relay, which actuates the feed water control valve.

The control valve is fully balanced, rugged and practically frictionless, the usual sliding stem moving in a stuffing-box being replaced by a horizontal rotating shaft.

Copes Flowmatic Regulator.

The equipment used in the Copes Flowmatic Regulator consists of the Copes patent Tension Type Thermostat, which instantaneously responds to water level changes; the Copes G.A. Regulating Valve with adjustable valve area and pressure compensation; and the Copes Flowmatic Controller.

The Flowmatic Controller is responsive to changes in steam flow, and participates in the movement of the feed regulating valve, with the action of the tension type thermostat. The

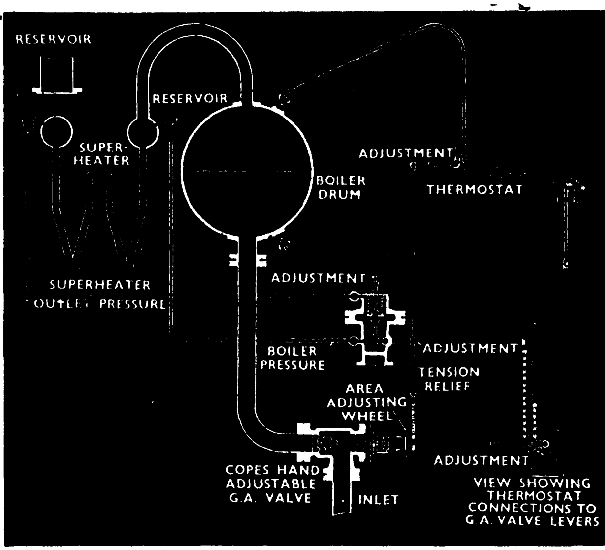

FIG. 2.—The Copes Flowmatic Controller.

rate of water flow to the boiler is thus correctly related to the steaming rate of the boiler in a manner which is impossible when water level control is used by itself.

Where automatic combustion control is used, the Copes Flowmatic Regulation is desirable.

THE COPES PUMP GOVERNOR.

The Copes Pump Governor is an automatically controlled balanced valve intended to be fixed in the steam supply main to the feed pump. The valve is operated by means of levers actuated by the difference of pressure between the boiler pressure and the feed-line pressure. The main steam header pressure (C) is carried to the inside of the sylphon bellows. The main water-header pressure (B) is carried to the outside of the bellows. The position of the weight on the lever arm determines how much the water pressure will be above the steam pressure. The amount of water that will pass through the control valve of the feed water regulator depends on the pressure drop across the valves as well as upon the area of the feed valve opening.

The governor maintains a fixed excess pressure between steam header and water header by varying the pump speed to correspond with the steam load on the boilers. As the steam pressure varies the water pressure should vary to correspond.

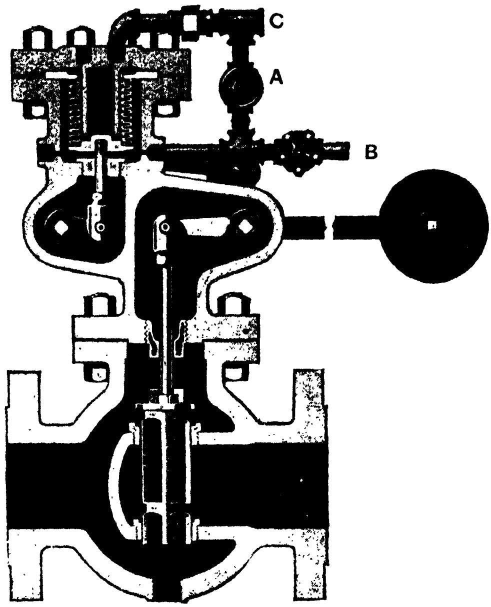

FIG. 3.—Copes Pump Governor.

CROSBY FEED WATER REGULATORS.

(*Crosby Valve & Engineering Co., Ltd., Crosby Works, Ealing Road, Wembley.*)

The action of this Regulator is in no way dependent upon the rising and falling of a float and there are very few parts which are liable to give trouble and so cause the apparatus to work in an erratic manner. This is an improved pattern Regulator and is furnished with an inclined power producer 'J,' shown in fig. 1, which will give continuous feed and is much simpler than the makers' original type of power producer.

The Regulator is very simple in design and there are no complicated moving parts to get out of order. In starting up the Regulator, it is only necessary to remove the air valve 'B' on the power producer and fill with water, it being so designed internally that there are no risks of air locks, etc. Once filled, the regulator will operate indefinitely without further attention.

The water level of the boiler is governed by the amount of water in the power producer. Thus it is possible to lower the water level of the boiler at any time whilst under load, or raise the control level. To lower the level it is only necessary to slack off the air valve nut 'B' and allow sufficient water to escape from the closed system to bring the boiler water to the desired point.

With this inclined Pattern Feed Water Regulator, as outlined above, the water level in the boiler is so maintained that a very reasonable line is given on the water flow meter chart, which is a great advantage where accurate records are kept. This is accomplished without even the use of an Excess Pressure or Differential Regulator on the inlet side of the boiler feed regulating

valve. If the excess pressure regulator 'S' is installed in conjunction with this type of feed regulator, and the makers strongly recommend that it should be to obtain the utmost efficiency and satisfactory control, then a uniform line can be maintained.

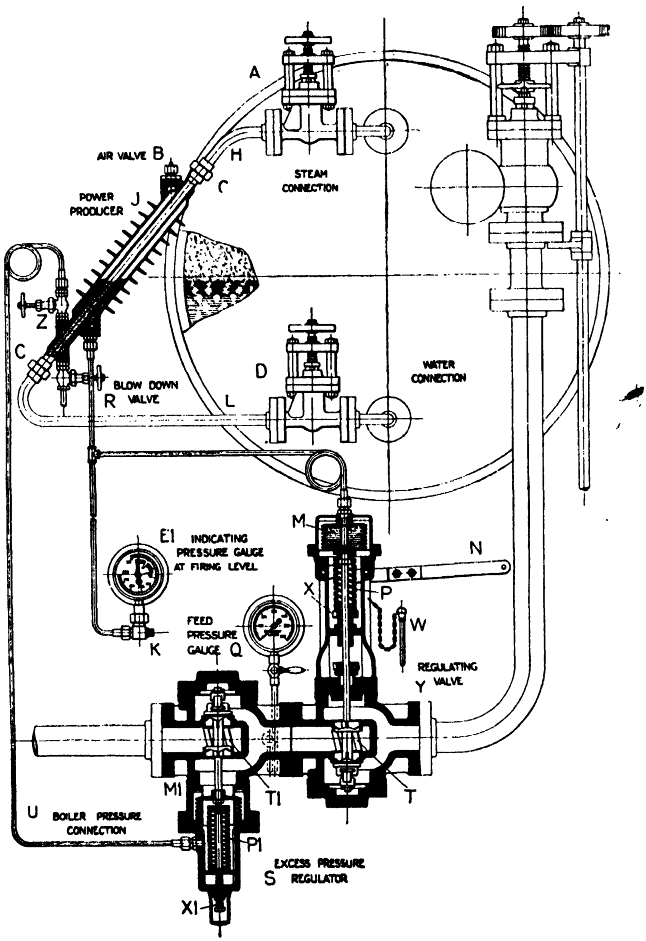

FIG. 1.

The regulating valve 'Y' is of a special double-seated semi-piston balanced type, having gradual opening ports giving accurate regulation of the water flow. This regulating valve can be equipped with a four-ply Sylphon seamless metallic bellows 'M,' as shown in the illustration, or a reinforced rubber diaphragm.

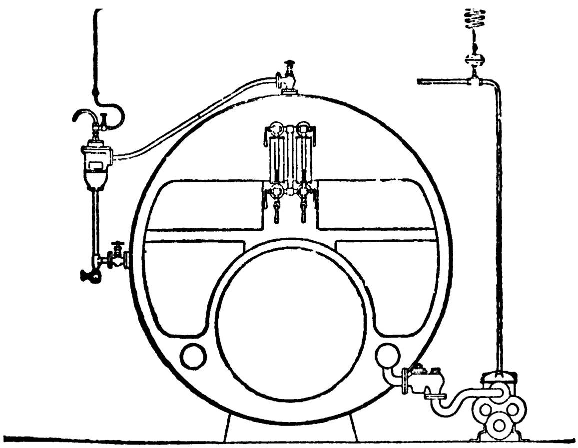
A feature of the Crosby Regulator is the indicating pressure gauge 'E1' fitted at the firing level, which gives a visible indication of the position of the regulating valve, whether 'shut' or 'open.' With the Crosby system of feed water regulation, the regulating valve can be in any position in respect to the power producer.

THE THERMOFEED REGULATOR.

(*Ronald Trist & Co., Ltd., Bath Road, Slough.*)

The 'Thermofeed' Regulator is designed to maintain an almost constant water level in a steam boiler. The variation is approximately ½ in. in Lancashire type boilers, and slightly more in vertical, economic and watertube boilers.

The 'Thermofeed' regulator consists of a float chamber containing a float-operated mechanism, which operates a double-seated valve. This valve controls the passage of steam to a 'Thermofeed' control valve or 'Thermofeed' automatic regulating valve, which is fitted either in the steam supply pipe leading to the boiler feed pump (as shown in the illustration), or in the feed line to the boiler, depending upon the lay-out of the installation.



A feature of the 'Thermofeed' Regulator is that the valves fitted in the feed line or the steam line to the pump are in the fully open position until they are closed by the operation of the 'Thermofeed' regulator.

Upon the 'Thermofeed' regulator being put out of commission these valves automatically resume the fully open position, permitting the feed supply to the boiler to be hand controlled.

From the illustration it will be seen that the float chamber is mounted externally to the boiler, and that the steam and water stop valves are provided to permit the examination of the equipment even with the boiler under steam.

THE WEIR 'ROBOT' BOILER FEED REGULATOR.

(*G. & J. Weir, Ltd., Cathcart, Glasgow, S.4.*)

This regulator is designed to maintain a steady, continuous feed at all rates of evaporation. It is very sensitive to small changes in water level, and contains no springs, diaphragms, or thermostats. The action is not affected by excessive pressure differences across the regulator, and as the single mitre valve gives a positive shut-off, it can be operated on boilers which are banked, hand regulation being unnecessary.

The action of this regulator (fig. 1) is as follows: When the float J falls, due to a fall in the boiler water level, the needle valve H rises, cuts off the flow of water through the opening

K into the chamber D, and the pressure in the chamber D falls, due to the leakage of water from the chamber through the clearance between the piston B and the cylinder C. Immediately the water pressure in the chamber D falls below the pressure for equilibrium, the valve A lifts and allows feed water to pass into the boiler. The valve A can rise only the amount that the needle H has been raised, because immediately the opening K is uncovered the pressure on top of the piston B rises above the pressure necessary to maintain the valve in equilibrium, and a closing movement of the valve A takes place until the pressure in the chamber D reaches the equilibrium value.

When the water level in the boiler rises, needle H is lowered and opening K is uncovered, thereby allowing pressure water to pass into chamber D and valve A falls to the same extent as the needle.

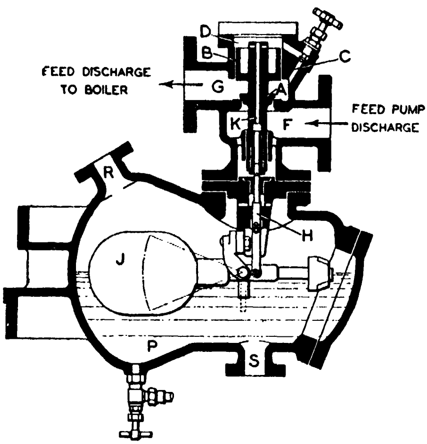


FIG. 1.—Weir 'Robot' Boiler-Feed Regulator.

It will be seen that the valve A and the piston B are constrained hydraulically to move in the same direction and to the same extent as the needle H, which is operated by the float; and for any given position of the needle H the valve A is maintained in equilibrium in a corresponding position.

The working water level in the boiler varies from a top level, when no steam is being generated in the boiler, to a bottom level when the boiler is operating at its maximum rate of evaporation, and the feed regulator maintains a steady water level between the top and bottom water levels for any given rate of evaporation between no load and the maximum load.

THE WEIR 'MUMFORD' FEED WATER REGULATOR.

This is another type of float-controlled automatic boiler feed regulator, also operated by the discharge pressure of the feed pump as in the 'Robot.' In the Weir 'Mumford' type, however, the float gear with needle valve is separate from the special check valve, connection between the two being made by means of a small copper pipe. The check valve is provided with an extension spindle with a piston, controlled by hydraulic pressure. The float rises or falls with the boiler water level, opening or closing the needle valve, and thus controlling the flow of water past the balance piston of the valve; when the needle valve closes, pressure is built up beneath the piston, and the valve opens, while when the needle valve opens, the pressure is released and the valve shuts.

FEED WATER HEATERS.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S. 4.)

The location of feed heaters in the system determines the type of heater which can be used. Heaters placed on the suction side of the feed pump may be of the direct-contact type, but on the discharge side of the feed pump they must be of the surface type, and being subjected to the full discharge pressure of the pump must be constructed accordingly. In the Weir 'Multiflow' feed heaters the heating surface consists of solid drawn copper tubes of heavy gauge, securely expanded into cast iron headers of substantial section. The entire element of tubes is free to expand, being held at one end only, and the construction avoids the leakage troubles inseparable from the use of ferrules and packing exposed to the variations of temperature in apparatus of this class. Vertical and horizontal heaters for all duties are manufactured.

De-Superheaters and Safety Valves.

THE CROSBY DE-SUPERHEATER.

(Crosby Valve & Engineering Co., Ltd., Crosby Works, Ealing Road, Wembley.)

This arrangement is designed to reduce automatically the pressure and temperature of high superheated steam by spraying the steam with water.

The outfit can be used in conjunction with a steam pressure reducing valve where this is necessary, or as a straightforward de-superheater without pressure reduction.

The use of a de-superheater enables steam which has been generated in modern high temperature plants to be used in connection with the older prime movers, process plants, auxiliary engines, etc., designed for low temperature steam.

For reducing the pressure the 'Crosby Patented Relay Operated Single Seated Balanced Valve' is used. It is fitted between the high pressure steam main and de-superheater and will deal successfully with any quantity of steam from the minimum to the maximum without hunting. The device has a cast steel body with special heat resisting nickel alloy valve and seat and is furnished with a balancing piston and gradual opening 'V' ports. The valve is operated by a hydraulic relay through chain led over suitable guide pulleys and connected to the level of the balanced valve. The relay consists of a hydraulic cylinder mounted upon a diaphragm chamber which is in communication with the low pressure steam main. The load on the diaphragm is balanced by means of a weighted steelyard which is connected by a bridle to a small 'pilot valve' and any movement of the diaphragm, due to a slight variation above or below the pre-determined pressure in the controlled or low pressure main causes this pilot valve to admit water to the top or bottom of the piston as the case may be. The movement of the piston operates the balanced valve in the steam main controlling the reduced pressure within very close limits irrespective of the volume of steam passing or variations in the high pressure main. The low pressure steam now passes by means of a connecting pipe to the inlet of the de-superheater chamber, this piping and the de-superheater being protected from an excess pressure by Crosby Pop Safety Valves with forged steel nozzles and nickel alloy parts, the number depending upon the pressure, size of main, and degree of safety required.

For temperature reduction the de-superheater chamber consists of a mild steel vessel with electrically welded seams, generally provided with a single pressure loaded, self-cleaning and self-adjusting spray nozzle so designed that sufficient pressure is always maintained at the nozzle to provide an efficient and fine spray. To regulate the admission of spray water to this spray multiple diaphragm control valves are provided, set so that they come into operation in sequence and thus give a means of accurately controlling the quantity of water admitted to the spray. The operation of these valves is in turn controlled by means of a bi-metallic type thermostat fitted on the outlet side of the de-superheater through a suitable bend or tee piece in the steam main. This thermostat regulates the admission of water through a small nozzle thus varying the pressure in the connecting pipe between the thermostat and the diaphragm control valves, causing these to open or close and thus varying the quantity of water sprayed into the steam. The water supply for the spray must be at an excess pressure of about 40 lbs. over and above the low pressure de-superheated steam. This may be taken from the feed main through a strainer and reducing valve or in large plants a separate supply is sometimes provided. The water for operating the hydraulic relay of the reducing valve and the thermostat should preferably be taken from an overhead tank so that the valves will work under a steady static pressure. A relief valve should be provided between the hydraulic reducing valve and the diaphragm control valves to protect these against any excess pressure and a back pressure valve is fitted to prevent steam passing into the hydraulic main should the water supply be cut off for any reason.

NOZZLE TYPE SAFETY VALVES.

(Crosby Valve & Engineering Co., Ltd., Crosby Works, Ealing Road, Wembley.)

These valves, which are fully protected by various patents, are manufactured in many designs to suit a wide range of operating conditions. The valves have exceptionally large discharge capacities far exceeding those of an ordinary bevel seated type of valve.

The discharge capacities realised are guaranteed and are achieved through a patented secondary lift which gives a full lift to the valve. These valves give their capacities with an accumulation not exceeding 3 per cent. and the blowdown, which is adjustable, can be varied between 2 per cent. and 4 per cent., both figures comparing favourably with the Board of Trade allowance of 10 per cent. The valves open and close sharply without any simmering or 'warn.'

For high pressure service these valves incorporate a full length nozzle as illustrated in fig. 1, which is manufactured from a special alloy steel highly resistant to erosion and corrosion. This nozzle is correctly shaped to give maximum flow and is so designed that the high pressure only comes in contact with the inside of this forged steel nozzle, thus the body is protected from excessive strains or distortion. The disc is also manufactured from a special forged high nickel chrome steel.

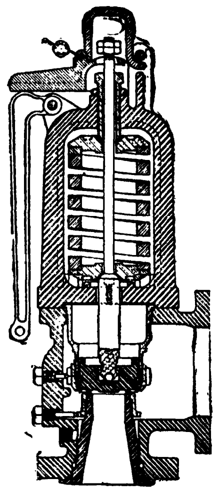

FIG. 1.

Crosby Nozzle Type Safety and Relief Valves can be furnished to suit pressures up to 2,000 lb. per sq. in. and temperatures of 1,000° F.

These valves are being used extensively for high pressure boiler plants and in oil refineries, etc. For oil service the valves can be supplied with totally enclosed spring bonnets, packed easing levers, etc., being perfectly tight on the discharge side.

Various modifications in the design of the easing lever, spring casing, etc., are available to suit individual requirements. Where necessary all the internal parts can be supplied of stainless steel to resist corrosion and for use on oils and oil vapours which would attack other metals.

THE KLINGER VALVE.

(*Richard Klinger Ltd., Klingerit Works, Sidcup, Kent.*)

The Klinger Piston Valve, fig. 1 (p. 1251), being seatless, eliminates all the troubles inherent with the ordinary seating valve. There is no seat to skim up, no valve to grind in and no gland to pack. The valve consists of a simple parallel piston sliding inside two resilient "Klingerit" compressed asbestos packing rings (marked A and A1 in illustration), which are separated by a ported lantern bush and held in place by the cover. Tightness of the valve is maintained by the pressure of the packing rings against the smooth surface of the piston.

When after prolonged use wear takes place it is corrected by tightening the cover nuts, thus compressing the rings further against the piston. When finally further compression is impossible the rings can be easily and quickly renewed at a very low cost, thus making the valve as good as new again.

An indicator on the handwheel shows clearly the position of the valve at any time and allows accurate control of the flow through the valve.

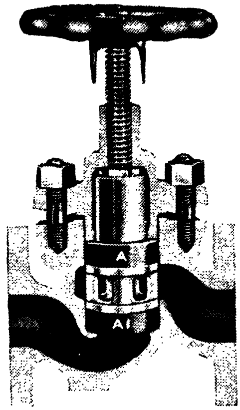

FIG. 1.—Section through Gunmetal flanged straight through "Klingerflow" Piston Valve.

These valves, it is claimed, show up to particular advantage when used under very strenuous conditions, such as continuous operation on throttling, as the parts on which their tightness depends are not directly subject to the scoring action of the passing fluid.

Klinger valves are made of various materials for use with saturated or superheated steam, hot oils and spirits, hydraulics, gases and chemicals, and are made in all sizes up to 10-in. bore. Special valves can be supplied for pressures as high as 1,500 lb. per sq. in.

'Newman-Milliken' Valves.

(Newman, Hender & Co., Ltd., Woodchester, Glos.)

The 'Newman-Milliken' glandless lubricated plug valve is of simple construction and possesses very few component parts. This valve is claimed to be free from the inherent defects of the taper plug cock and to have advantages over gate and globe valves. Primarily intended for low-temperature services not in excess of 365° F., it is suitable for handling a wide variety of products, including petroleum derivatives, acids, gases, water, compressed air and so forth at pressures varying from vacuum to 3,000 lb. per sq. in. It is made in sizes from ½ in. to 12 in., with screwed or flanged connections.

Referring to the accompanying sectional view (fig. 1, p. 1252), it can be seen that the design embodies a parallel plug without any form of packing, which has a shoulder on the upper portion, butting up against a corresponding shoulder machined in the head of the valve body. The plug is forced tightly against the body head by the pressure exerted by the spring within the bottom cover. Sealing is effected by means of a suitable plastic compound or lubricant, which is stated to ensure an entire absence of sticking. Different lubricants are employed for different services, but each of these lubricants is quite insoluble and is stated to have no deleterious effect on the liquid or gas passing through the valve. A reserve of lubricant is contained in the space below the lubricant screw and it is fed through a ball check valve, upper horizontal lubricant duct, vertical ducts, and a lower duct, thus lubricating the plug shoulder and working faces. The lubricant is maintained by this screw-feed arrangement at a pressure equal to, or greater than, that of the liquid or gas controlled by the valve. Should the valve show any tendency to leak it is only necessary to give a turn or two to the screw to stop it so doing.

When the valve is closed the pipe line pressure is prevented from escaping into the outlet port, for the pressure keeps the plug tightly in contact with the outlet side of the body, making a seal with the lubricant throughout its length. In addition, under these circumstances, the pressure moves the plug away from the inlet side through a distance of about half a thousandth of an inch, so that the pressure acts beneath the plug. As a consequence, the higher the line pressure the tighter the valve will hold, both in the port and at the head. It will be seen that the plug support spring only helps to keep the plug firmly against the body head and consequently to keep the

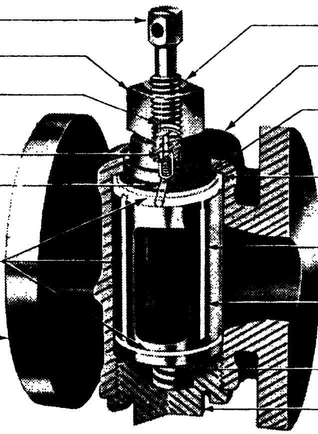

FIG. 1.

valve tight at this point. For high-pressure services the force exerted by the spring is small compared with the force produced by the line pressure, but on low pressure or vacuum services, of course, the opposite is the case.

A feature which is stated to be unique is the provision of a visual check on full lubrication, for when the valve is fully lubricated excess lubricant is forced out between the shoulder of the plug and body. Hence lubricant cannot be forced into the pipe line by excessive application of the lubricant screw. A further advantage of the design is that, since a parallel plug is employed, the plug cannot leave its seating (as happens in the case of a taper plug) when it is lifted to ease the turning movement; therefore, no space is created between the plug and the body for the inclusion of foreign matter, with the possible danger of subsequent scoring taking place.

This type of valve is manufactured in a number of patterns, with rectangular or round ports. Both rectangular and fully round ported valves provide a full pipe area opening, and the last-named are particularly suitable for all abrasive services, or where solids are present in the pipe line. Illustrated in fig. 2 is one of the standard cast iron valves, suitable for working pressures to 200 lb. per sq. in. and for any service in which cast-iron or steel will not be attacked by the liquid or gas. It is made with the body, plug, and bottom cover in cast iron of a fine close-grained structure. The lubricant set screw, ball, and ball seat are of mild steel and the plug support and ball check springs are of oil-tempered steel. These valves are also made in cast steel, gun-metal, acid-resisting bronze, Ni-resist, Aterite (for weak sulphuric acid), and various other metals. Geared operation can be fitted to all valves when so desired.

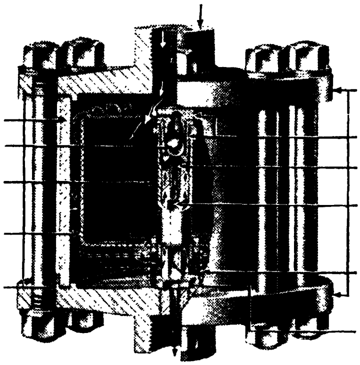
FIG. 2.

Newman-Carter Steam Traps.

FLOAT TYPE.

(Newman, Hender & Co., Ltd., Woodchester, Glos.)

HEAVY ENDS WITH FULL DEPTH TAPER THREADS FOR PIPE.



DESCRIPTION OF TRAP.

The body of the standard 'Newman-Carter' trap consists of a steel tube 'A' with massive cast-iron covers 'B' and 'C' at each end held together by an ample number of steel studs and nuts. The joint rings between these parts are very thin and made from graphited asbestos of high quality. For working pressures above 200 lb. per sq. in. the flanges are made either from steel castings or fabricated from steel plates.

All the working parts are attached to the bottom flange 'B' so that when cleaning or repairs are necessary the body tube and bottom flange can be removed and access gained to these parts without removing the complete trap from the pipe line.

The working parts of the trap consist of a brass hexagonal centre pillar or guide 'D' which is screwed into the bottom cover 'B,' the joint being made by means of a corrugated nickel alloy ring. The seating 'E' is of Monel metal which is pressed into a tapered hole of standard size in the top of the centre pillar 'D.' A brass float tube 'F' is attached to the brass float 'G' by means of nuts of the same material. The float 'G' is balanced by a stainless steel spring 'L' and so can be made of heavy gauge material, giving a great advantage over other steam traps where the float has to be made from material of a very thin section to function correctly.

The valve cage 'H' is attached to the upper part of the float tube 'F' into which it is screwed and locked in position by the lock-nut 'J.' The valve consists of a non-corrosive steel ball 'K' which is quite free to move about in the cage 'H,' this cage only being used to place the ball on the seat 'E' when closing and to lift the ball clear of the seat 'E' when opening to discharge. It should be particularly noted that it is the pressure only that keeps the ball valve 'K' closed and when in this position it is independent of any movement of the float. Furthermore it is only the very small weight of the ball which contacts with the seat and this contact is not accentuated by the weight of either float or levers as is the case in other traps of the Bucket or Inverted Float type. For this reason repairs to valve or seat in the 'Newman-Carter' trap are rarely, if ever, required.

OPERATION OF TRAP.

Steam and condensate enter the trap at the top which must be filled with water on installation. The condensate keeps the balanced float full and overflows into the trap body. The water gradually rising in the body lifts the float which in turn opens the ball valve and discharges the condensate at the bottom of the trap. As the level of the water in the trap body falls, the float drops and allows the valve to close before all the water in the body has been blown out.

The 'Newman-Carter' trap cannot blow steam unless the ball valve is held off its seat by dirt or other foreign matter. It is almost impossible for this to occur, as the ball is never lifted from its seat for more than a quarter of the diameter of the discharge orifice, so that anything that can get under the ball can pass through the orifice.

When the amount of condensate is high, the trap discharges continuously, as the ball valve is kept a certain distance off its seat according to the rate of condensation, but when the volume of condensate is low, the trap works intermittently. The ball valve closes tightly on its seat when there is no condensation and is held in position by the steam pressure.

ADVANTAGES OF TRAP.

1. The trap is simple and very robust in construction whilst relatively large discharge capacities are obtained without the complication of levers.
2. The ball valve is absolutely free and independent of any float movement. It is continually changing its position and finds a fresh seating surface every time the trap shuts off.
3. Wear on the valve seat is reduced to a minimum as this seating has only to support the free ball. The ball is so light that the contacting action which takes place does no damage to the seat or itself even after extended periods.
4. It works equally well on steam or compressed air lines.
5. Will function perfectly when a number of traps are connected in parallel.
6. There is only one type of 'Newman-Carter' trap and this is suitable for all service conditions.
7. It is of light weight.
8. As the inlet of the trap is at the top, it is unnecessary to fit air vent cocks.

'THE BRADFORD' STEAM TRAP.

(*United States Metallic Packing Co., Ltd., Soho Works, Allerton Road, Bradford.*)

'The Bradford' Steam Trap embodies a new principle in this class of device. It is a float trap, but with an important difference. The float does not open or close the discharge valve. It simply releases or engages a weighted lever, which is so arranged that the outlet is instantaneously opened or instantaneously closed. There is no middle position. This effectually prevents the wire-drawing of the discharge, which cuts the valve and seat and so destroys the efficiency of those traps where the opening and closing take place gradually.

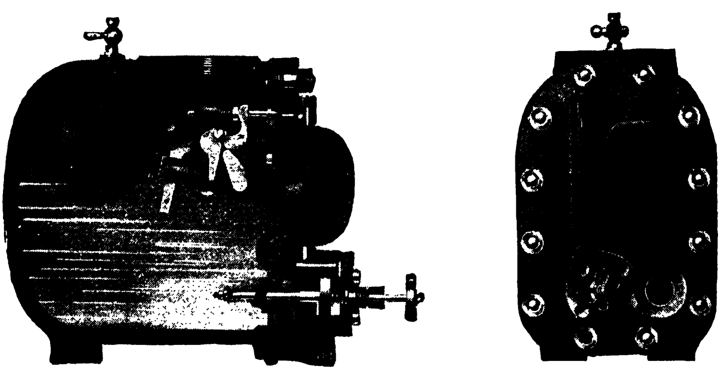


FIG. 1.—Piston Operated Trap.

The method of operation is as follows. The water accumulates in the collecting chamber and gradually raises the float until the latter reaches the desired point, when it trips the weighted lever, which immediately opens the discharge to its fullest extent. The water is then forced out under full pressure until it reaches the bottom level, when the lever is again tripped and the discharge is at once closed. The outlet is always submerged, so that there can be no escape of steam.

The apparatus is made in two classes, viz. the piston-operated trap and the direct-operated trap. Fig. 1 represents the piston-operated trap, in which the discharge valve is operated by the steam acting on a piston working in a cylinder. By this method the maximum diameter of outlet opening is obtained without reference to the steam pressure. This is a most important feature, as in consequence of the unusually large outlet the trap will deal equally well with flooding and priming as with ordinary condensation. In the direct-operated trap the action is simpler, the discharge being opened and closed directly from the trip lever, but the area of the outlet is smaller.

The traps will work at any pressure from 650 lbs. downwards, and are made in several sizes. The piston-operated traps will discharge from 1,000 to 6,000 gallons per hour when working at 100 lbs. pressure. In the direct-operated traps the discharge capacities range from 200 to 1,200 gallons per hour at 100 lbs. pressure. Both traps will force the discharge water 1 foot high for every pound of steam pressure.

An *eliminator*, which combines the above trap with a convenient form of separator, is also prepared, the manufacturers being The United States Metallic Packing Co., Ltd., of Soho Works, Allerton Road, Bradford.

Valve Refacers.

THE SIMPLEX PATENT VALVE RESEATING AND FACING MACHINE.

(*W. Crockatt & Sons, Ltd.*, 62 *Darnley Street, Glasgow, S.* 1.)

(1).

This tool, fig. 1, has been designed to avoid the necessity of using the studs in the valve chest as a means of steadying. At the same time it is simpler and stronger than the machines which are secured and centred by means of a chuck operated by a scroll. A very important feature is that the seat being faced is *visible* during the facing operation.

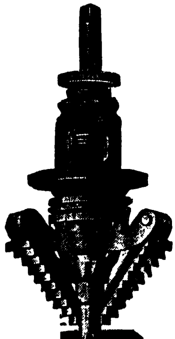

FIG. 1.

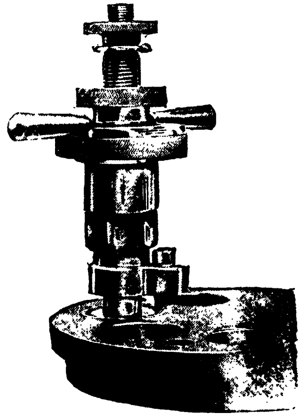

FIG. 2.

The tool is fixed in the valve chest (which may be either plain or screwed) by means of three stepped arms, pivoted at their upper ends. These arms are expanded by a cone which is depressed downwards by means of the hand nut. The action of expanding these arms both centres the tool in the valve and fixes it securely in position. This is ensured by the manufacture of the tool, the arms being turned up truly central with the spindle, after assembling. The cutters used are made of flat steel, and one end is arranged for flat and the other for bevelled seats. The simplicity of this type of cutter is found to counterbalance any slight advantage the milled type

of cutter may have. Also a very much smaller number of cutters can be employed to deal with a large range of valves, as each cutter is adjustable. In order to prevent chattering of the tool, the feed is against the action of a strong spring, which keeps an upward pressure on the tool, so that feeding only takes place when the cutter is forced down by the action of the nut. This prevents the cutter following any irregularities in the face of the seat.

A simple attachment is provided when desired for trueing up the valves themselves. The valves are centred in this part of the tool and faced up by a movable tool, which can deal with either flat or bevelled valves. The arms and lower part of the body of the tool are made of cast steel, so that the machine will stand hard wear. Ball-bearings are fitted throughout to ensure smooth working and to avoid jarring.

The machine is made in five standard sizes to deal with valves from ¾–12 ins. diameter, but has been supplied and can be easily adapted to do valves even larger.

(2)

In order to meet the demand for a tool which will face up the seats of the group valves in Weir's and similar feed pumps, the Simplex No. 3 machine has been introduced. This tool, fig. 2, is secured in position by the expansion of three segments, which are turned concentric with the central spindle, and which are expanded hard against the inside of the bore of the valve seat by the action of the tapered end of the spindle. It can easily be adapted to flat or bevelled seats by simply changing the cutter used.

If it is desired to face up the valves in the bottom seat of the pump without drawing the complete seat, a special tool with an extended body can be supplied.

Besides being suitable for the type of valve mentioned, the tool is equally adaptable to dead-weight safety valves, or, indeed, to any design of valve in which the inside of the bore is a plain cylindrical surface. Ball-bearings are fitted to ensure smooth and easy working.

Tube Cleaners.

THE CROCKATT SIMPLEX TURBINE TUBE CLEANER.

(W. Crockatt & Sons, Ltd., 62 Darnley Street, Glasgow, S. 1.)

This appliance (fig. 3) is made in sizes from 1¾ ins. upwards, and is driven by a turbine suitable for water at about 100 lbs. pressure. The cleaning head is detachable, so that special cutters or

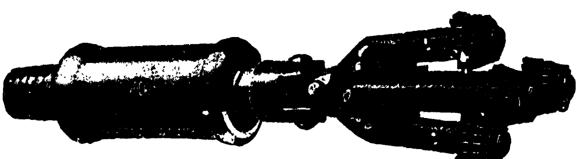

FIG. 3.

brushes may be attached to suit different conditions, and the universal joint enables the too to be used in curved tubes, such as in Stirling boilers. It is suitable also for Babcock tubes, economiser tubes, and any other kind of pipes having hard scale.

Salinometers.

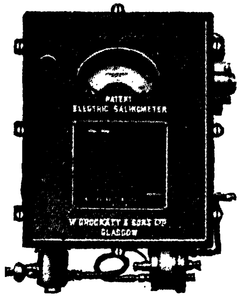
THE CROCKATT SIMPLEX PATENT ELECTRIC SALINOMETER.

(W. Crockatt & Sons, Ltd., 62 Darnley Street, Glasgow, S. 1.)

This is a direct reading instrument showing the amount of salt or other dissolved impurity in water, in grains per gallon, or other convenient measurement.

The illustration shows the standard Admiralty type, which is calibrated from 0 to 0·5 grains of chlorine per gallon and compensated for temperature variation of the water, between 60° and 120° F. This type has been fitted to cruisers, destroyers, etc., in the British and many foreign navies, as well as on liners, in power stations, etc.

Where a number of points are to be tested, the Multipoint pattern is fitted. In this, there is only one measuring instrument for any number of testing points, and it is mounted on a control board which also carries interlocked selector switches (one for each point), with corresponding



relays and warning lamps. When salt is present the warning lamp glows and the actual amount of salt present is noted by switching in the corresponding compensator box (which is very similar to the self-contained instrument illustrated, but has no instrument). The Multipoint type has the advantage that the readings of the various condensers, evaporators, etc., are obtainable on the one board, which can be mounted in a convenient central position. Also, where a large number of points have to be tested for water purity, it is cheaper than the corresponding number of self-contained instruments. A notable installation is one of 16 points on s.s. *Queen Mary*, and also her sister ship, *Queen Elizabeth*.

In addition to these instruments, which are used for testing the purity of the condensate, distilled water, etc., the same manufacturers make a Boiler Density Tester, which indicates the density of (or amount of dissolved matter in) the water in the boiler. This instrument is of great value as a protection especially for watertube boilers, where only impure feed is available. It is also an aid to economy, as it saves unnecessary blowing down of the boiler.

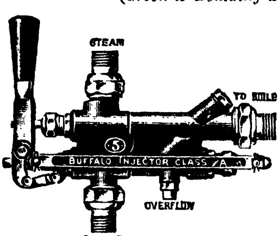
The latest modification is the Brine Density instrument which indicates the concentration of the brine in evaporators.

Special instruments have also been supplied for testing the concentration of sulphuric acid, during manufacture; testing for leakage of glycerine in Soap Works, and other industrial applications.

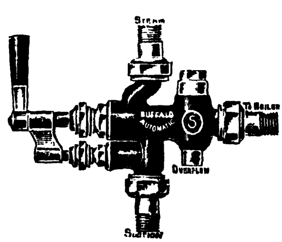
Injectors.

THE BUFFALO AND BISON INJECTORS.

(*Green & Boulding Ltd.*, 162*a* *Dalston Lane*, *London*, *E.* 8.)



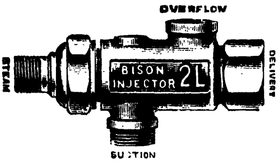
Class A.



Class B.

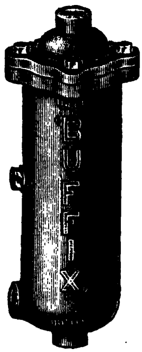
The Class A Buffalo Injector illustrated above is a double tube injector capable of taking either hot or cold feed water and is operated entirely by one handle. The lower tubes raise the water and supply it under pressure to the upper ones thereby enabling hot water (according to the steam pressure and other factors) to be taken. It has a positive shut-off overflow, thus eliminating dribbling, and the entrainment of air. The water supply adjustment is incorporated in the Injector.

The Class B Buffalo Injector is of the single tube type. It is a re-starting Injector and requires no vlave in the suction pipe for regulation.



The Bison Injector is particularly suitable for use with low steam pressures and may be fitted either submerged in the feed tank or with the feed water flowing to it.

Compressed Air or Steam Cleaners and Dryers.



THE "BUFFIX" SEPARATOR.

(Green & Boulding, Ltd., 162a Dalston Lane, London, E. 8.)

The Buffix Separator is a device for cleaning and drying compressed air or steam. The air or steam entering at the top has a centrifugal motion imparted to it, causing the water, oil and other impurities to be thrown out to the side of the container and so out through the drain. The clean, dry air or steam passes out at the bottom. It is a purely metallic type of cleaner and contains no felts, pads, etc., to become sodden; the pressure loss incurred is thus negligible but the degree of separation is extremely high. The Buffix Separator should be fitted as near to the point at which the air or steam is used as is possible so as to enable it to deal with condensation occurring during the passage through the pipe line.

Jointing Material.

(Richard Klinger Ltd., Klingerit Works, Sidcup, Kent.)

"Klingerit" Jointing was invented over sixty years ago and was the first compressed asbestos fibre jointing material to be made. Recent scientific developments have enabled its quality to be improved, and it is now a universal jointing material which can be used for superheated steam at the highest working pressures and temperatures, as well as for acids and other chemicals and all types of oils, spirits and other hydro-carbons.

It is made in thicknesses from ·008″ to ¼″ and can be supplied in sheets as large as 80″ × 240″ and is available also with graphited finish.

COMPRESSED ASBESTOS FIBRE JOINTING BONDED WITH SYNTHETIC RUBBER COMPOUND.

(Turner Brothers Asbestos Co., Ltd., Rochdale.)

Compressed asbestos fibre jointing made by Turner Brothers Asbestos Co., Ltd., asbestos manufacturers, of Rochdale, under their mark 'OAF,' is a sealing medium which for many years has held an important part in the functioning of steam plant and has helped in no small way to achieve the increased steam pressures prevailing in modern engineering practice.

Turner Brothers Asbestos Co., Ltd., make special qualities of 'OAF' incorporating ingredients resistant to acids and oils which fulfil a need for an effective seal and have already found a ready field in the chemical industry and in oil refinery work. Other specialised uses are covered by OAF' jointings made to Ministry of Aircraft Production, Admiralty, etc., specifications.

'OAF' Jointing is made from selected asbestos fibre and a special compound bonded together under pressure into a pliable and resilient sheet.

It is well known that there has been a serious curtailment in the supply of natural rubber and because of this it has been necessary to undertake the development of the use of synthetic rubber. It is, therefore, gratifying to be able to record that the Research Department of Turner Brothers Asbestos Co., Ltd., has successfully developed high grade 'OAF' jointings by the scientific blending of a percentage of synthetic rubber in the bonding compound.

'SEATRIST' RINGS.

(Ronald Trist & Co., Ltd., Bath Road, Slough.)

It is claimed that this automatic packing ring is correct in practice and theory. Fluid pressure reacts on a flexible tongue or lip : the higher the pressure the tighter the seal. Therefore maximum sealing efficiency with no following-up and a minimum of wear.

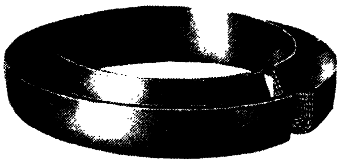


FIG. 1.

Fig. 1 shows the 'Seatrist' gland ring which is still fundamentally the same as when manufacture started more than 40 years ago. Note the tongue tapered to a wedge furnishing flexibility with strength and the reinforced body and heel on the outside, giving stability and robustness, permitting the gland assembly to stand up as a unit to the shocks and pressures inevitable to its functioning. One ring nests into the next behind from which it receives support without interference of its automatic operation. This nesting has another good result; rings are held snugly to the ram or rod when the pressure is off.

One of the useful features of the 'Seatrist' ring is that it can be fitted split without interfering with its automatic action. The rings can therefore be opened by careful bending to fit over the ram or rod without dismantling. When 'cut' rings, as they are called, are used, more than a single ring must be employed. The normal assembly shown in fig. 2 comprises three rings with support rings, soft headers for low and medium pressures, metal headers or a combination of metal and moulded support.

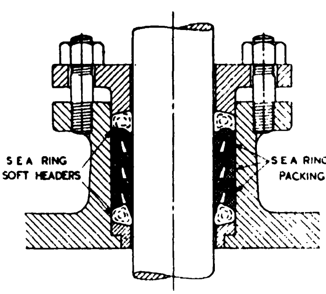

FIG. 2.

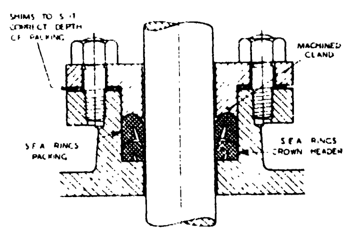

FIG. 3.

This last arrangement, termed a crown header, is very useful for shallow glands, with a single 'Seatrist' Ring which must be fitted uncut (fig. 3).

For use on pistons 'Seatrist' Rings have the flexible tongue outwards. For this reason they are called inverted 'Seatrist' Rings.

THE UNITED STATES METALLIC PACKING.

(*United States Metallic Packing Co., Ltd., Soho Works, Allerton Road, Bradford.*)

This packing is made in four distinct forms: 1, block type of packing; 2, cone or locomotive type of packing; 3, duplex type, consisting of combination of the block and cone types; 4, atmospheric-duplex type, specially designed for use on low-pressure condensing cylinders.

The United States Duplex Packing.

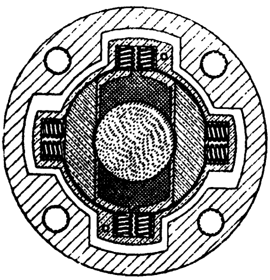

FIG. 1.

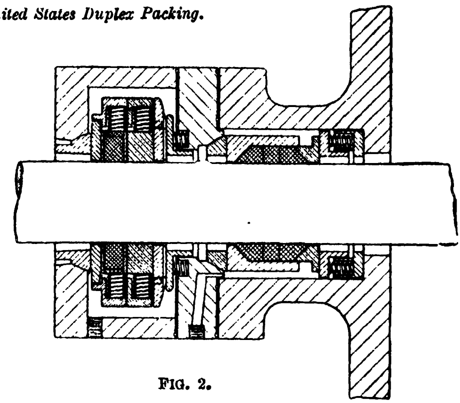

FIG. 2.

Figs. 1 and 2 show the duplex type of packing. The block portion consists of eight blocks which are held in strong rings, having pockets or horns holding springs. The packing blocks are put together in sections, four blocks to a section. Each section is, therefore, composed of two working blocks, Babbitt lined, and two guide blocks. The joints between the blocks in one section are at right angles to those in the other section, thus breaking joint. The blocks are regulated by springs, which merely keep the parts in place when steam is shut off, as when the steam is applied the steam pressure regulates and sets the packing. A ball-joint on one side and follower with springs on the other give the packing free play and keep it steam-tight, without regard to the vibration of the rod. It works equally well whether the rod vibrates or not, and, causing no friction, it does not wear the rod, but gives it a high polish. With efficient lubrication the blocks wear very slowly, many of the packings having given over twenty-four years' service without renewal of the blocks.

The cone portion of the duplex packing consists of three white metal or bronze rings placed in a floating cup, the interior of which is partly conical. This cup rests against ball and socket-ring, and the whole is kept in place by a follower with suitable springs, which allow the packing free play in all its movements. The whole is enclosed in a strong case, and bolted to the cylinder head with the usual stud bolts. The packing is steam setting, hence the friction is reduced at least 50 per cent. as compared with non-steam-setting packings. Drain valves are provided for removal of water, core sand, or other accumulations.

The block type of packing is used for pressures under 100 lb. per square inch. The duplex type is employed for pressures over 100 lb. Either packing can be arranged for working with steam superheated to 700° F.

Fig. 3 shows the cone or locomotive type of packing, which is practically similar to the cone packing described above. The white metal rings are the only parts which require renewal, and it is no uncommon thing for locomotives to run 80,000 to 100,000 miles without requiring adjustment of packing. All packings can be arranged to pass over enlarged ends.

Cone.

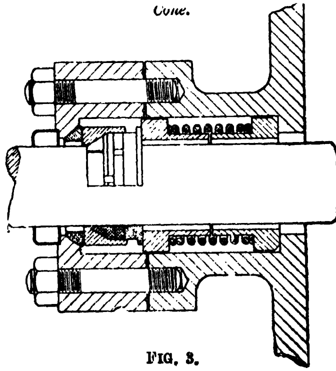

FIG. 3.

SECTION XXVII

PART V

Steam Condensers—Air Pumps—Circulating Screens—Cooling Towers.

THE WEIR 'REGENERATIVE' SURFACE CONDENSER.

(*G. & J. Weir, Ltd., Cathcart, Glasgow, S.4.*)

This condenser was introduced to eliminate the temperature loss which takes place between the temperature of the condensate and the vacuum temperature in normal type condensers, and also to give a condenser which delivers its condensate practically air or oxygen free. Consequently, although this condenser is suitable for any feed system, it is pre-eminently suitable for fitting to a closed circuit feed water system.

The design is the result of a series of researches carried out by G. & J. Weir, Ltd., and a typical example is shown in fig. 1.

It will be seen that a large lane is provided down the middle of the condenser, so that steam can penetrate right down to the bottom; this steam re-heats the condensate dropping from the lowest rows of tubes to practically steam temperature. Tests from actual plants show that the difference between the condensate temperature and the vacuum temperature does not exceed 2° F. This result is independent of the air leakage present. These tests also show that the oxygen contained in the condensate can reach as low as zero oxygen, 0·015 ml. per litre being quite a normal figure.

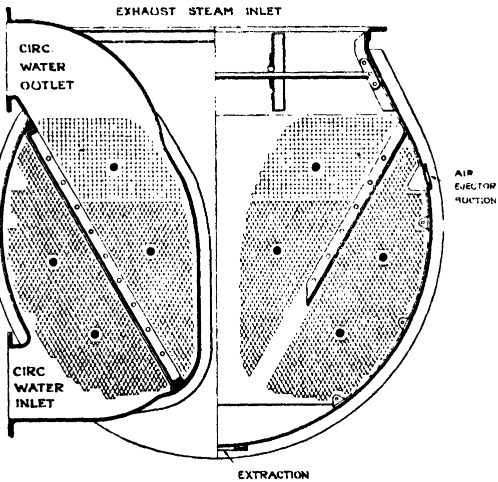

FIG. 1.

A hood plate is fitted on each side of the condenser, thus giving two reflex flows on the steam side; this arrangement permits a large surface to act as an air cooler if large air quantities are present, while if the latter are small the air cooling surface will be small. This action is automatic, the surface acting as an air cooler, automatically adjusting itself to the air quantity. This property results in the air being drawn off by the air pump at a minimum temperature for the conditions and ensures an enhanced condenser performance. The double arrangement shown lends itself to the twin water box design favoured by many present-day land engineers, the idea being that one-half can be shut down for cleaning or tube plugging while the other half is working, so that the main turbine need not be shut down.

The shape of the centre lane, together with the position and length of the hood plate, permits of a large entrance area being presented to the entering steam, with a gradually reducing area to the air suction, so that all the surface is equally effective and a minimum of pressure drop is attained.

THE WEIR ROTARY CONDENSATE EXTRACTION PUMP.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S.4.)

The Weir Rotary Condensate Extraction Pump has been specially designed for use with closed feed systems, and is capable of operating under a particularly low suction head. It possesses stable characteristics, and is therefore entirely suitable for operating in parallel.

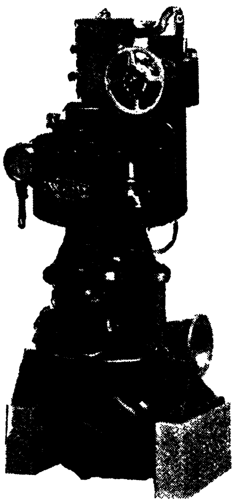

FIG. 2.

The vertical design of the pump permits the suction to be placed at the lowest point; this is important in ships having underhung condensers, where the head room available is small.

The Weir pump is of the vertical spindle, two-stage type, the lower impeller being the first stage and the upper impeller the second. The pump gland is arranged to be subjected to the full discharge pressure of the pump which effectively seals the gland and prevents any possibility of air entering the feed water.

The pump casing is divided down the centre line on a vertical plane, and suction and discharge branches are arranged on the rear casting. The pump may therefore be opened quickly and the shaft and impellers examined or removed without dismantling the remainder of the pump. The turbine is mounted on a flanged extension of the frame, and the drive is through a coupling which permits the power unit to be lifted clear for overhaul.

The turbine is of the impulse type, with one pressure and several velocity stages, and the unit runs at a relatively low speed.

A speed governor is provided, so adjusted as to maintain a reasonably constant speed between no load and full load. The usual emergency governor is also provided which closes the stop valve by means of trip gear when the speed of the pump reaches a predetermined limit. The turbine is fitted with roller bearings and ball thrust of substantial design.

The pump can also be arranged for turbine with geared drive or for electric motor drive as required. The impellers and armature are hung from an accessible thrust bearing at the top of the motor.

THE WEIR AIR EJECTOR.

(G. & J. Weir, Ltd., Cathcart, Glasgow, S.4.)

The three-stage ejector as developed by G. & J. Weir, Ltd., is illustrated in fig. 3 (p. 1263) and is used when the highest vacuum is required. On dry air tests these ejectors have attained vacua within 0·02 in. of the barometer; such extreme vacua, however, are seldom called for commercially, but this property enables them to reduce the partial air pressure in normal plants down to the very lowest limits. The saving in steam consumption of the three-stage type over the two-stage type is about 30 per cent. at 29 in. vacuum, and increases with higher vacuum. The three stages are generally similar in design, but are proportioned to suit the actual air, steam, and vapour volumes reigning at the respective stages. The steam nozzles are convergent, divergent, wherein the pressure energy of the steam is converted into kinetic energy; the steam issuing from the nozzles at high velocity (over 3,000 ft. per sec.) is delivered into a convergent, divergent diffuser nozzle; entrainment of the air and vapour takes place in the convergent portion of the diffuser, and the pressure rise takes place in the divergent portion; the combined mass of operating steam and entrained air and vapour pass to first intercooler, which is of the surface type and is arranged alongside and partly embraces the diffuser; the operating steam and vapour are condensed out in this cooler, while the air and its associated vapour pass on to the second stage, where the action is repeated, and so on to the third stage, the air being finally discharged to atmosphere.

The steam nozzles are of Monel metal to resist erosion, while the diffusers are of hard gun-metal.

The vertical design of intercoolers allows of the maximum air cooling and devaporising effect, so that the air is cooled and dried to a maximum for the conditions before it passes on to the next stage.

Between the discharge of the second stage and the inlet to the third stage a light plate non-return valve is fitted. This valve has the effect of stabilising the vacuum produced by the third

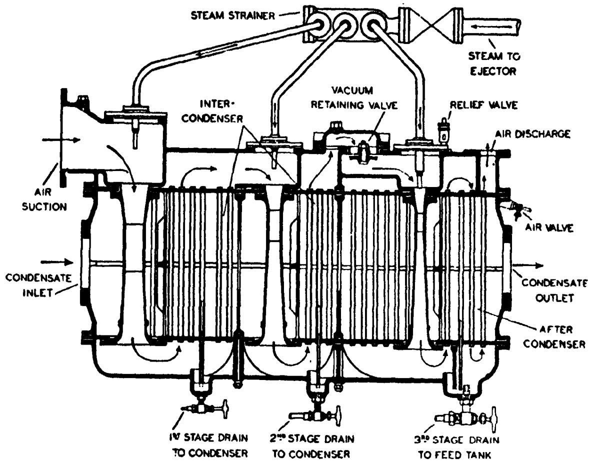

FIG. 3.

stage should the steam pressure fall below the designed figure. It also allows of the full vacuum being retained should the ejector steam valve require to be shut for any reason whatever; each intercooler is drained separately to the main condenser and the after-cooler to feed tank.

Circulating Water Screens.

(*F. W. Brackett & Co., Ltd., Colchester.*)

When water is taken from streams, rivers and tidal estuaries for cooling purposes to the condensers of power houses, it is necessary to remove from the water leaves, fish and other debris liable to choke the condenser tubes. For this purpose, mechanically operated self-cleaning screens are generally used, and the screen described here takes the form of two continuous chains carrying perforated panels through which the water flows. This screen band is revolved continuously so that the part which served to hold back the debris under water is brought up, automatically cleaned and returned to service.

The screening surface takes the form of a series of perforated and galvanised steel panels, which are attached to heavy type roller chains of either all steel, gunmetal or stainless steel construction to suit existing conditions. These chains are hung on sprocket wheels above ground level and dip down into a pit through which the water circulates, the chains and head-gear being housed in a fabricated steel framework sealed against the free passage of unscreened water. The water passes through the screen and is drawn off in a clean state, whilst the debris, which is caught on the outside of the screen, is elevated with the help of conveyor shelves to a point above ground level. The perforated panels above ground level are washed clean by a number of water jets, and the debris and wash water are diverted by a collecting hopper which discharges into a rubbish trough, which is itself led to a convenient point of outfall.

An important feature of this screen is that there are no working parts permanently under water.

The screening band is revolved by headgearing fixed in the frame above ground level, and is usually driven by an electric motor through a multispeed gearbox, so that the speed of revolution of the band may be related to the amount of debris in the water.

The type of screen just described is pre-eminently suitable for situations where the level of the water supply varies considerably, such as is the case with tidal waters, but for cases where the water level variation is inconsiderable the makers' 'cup' type screen may be preferable In this case the screening surface is arranged round the periphery of a large drum, the unscreened water flowing into the 'cup' and passing out through the mesh, otherwise the principle remains the same as for the 'band' screen.

'Cup' screens are now widely in use for screening sewage effluents and other factory wastes and also for waterworks, in which case fine mesh gauze is usually fitted. In the case of 'cup' screens, maintenance costs are claimed to be negligible, as there are practically no wearing parts.

PREMIER WATER COOLING TOWERS.

(The Premier Cooler & Engineering Co. Ltd., Shalford, near Guildford, Surrey.)

The Premier Cooler Co. manufactures all types of water cooling apparatus which depend upon the atmosphere for lowering temperatures by evaporation, by which means water may be cooled to within a few degrees of the prevailing wetbulb temperature, which is the theoretical limit of cooling by air.

These coolers are extensively used for re-cooling the water required by steam condensing plants, the jacket water of internal combustion engines, and many industrial purposes, and incidentally may be employed for removing gases from liquids and the evaporation of water from liquids containing solids which it is desired to concentrate as far as possible by this process.

The various types of water cooling apparatus in general use may be described as follows and the makers should be consulted as to the most suitable to meet any particular requirement.

Pond and Spray Cooling.—The simplest method of cooling is to discharge the warm water to an open pond of sufficient area to cool it to a low enough temperature by surface evaporation, which is very sluggish, making necessary a pond of large dimensions. The size of the pond may be greatly reduced by spraying the water from nozzles to obtain additional contact between water and air. These nozzles, which atomize the water, are carried on pipes placed a few feet above the surface of the water in the pond, but if an artificial pond has to be constructed the initial cost of this system may be greater than that of a cooling tower with its smaller tank. In high winds water loss from spray plants is heavy even when louvres are fitted round the edge of the pond, which interfere with the air flow on still days, and trouble may be experienced from clogging of the nozzles by foreign matter in the pond.

The cooling results from sprays cannot equal that of a tower occupying much less space and the pumping head may not differ materially in either system.

The Chimney Type Tower, which is almost invariably used for the larger schemes, is made in rectangular or circular form with a height ranging from 70 ft. upwards, designed to resist the full wind pressure experienced with a good factor of safety without the assistance of the internal filling or irrigation. These towers are generally of timber comstruction, but they can be supplied with steel, concrete, or brick chimneys. In the wooden construction all the bolts, fishplates, grappling irons, etc., are heavily galvanised.

The irrigation system is designed to give the largest area possible for the uprising air, which is brought into contact with the water or other liquid to be cooled or evaporated, in the finest possible form. The towers operate on the drop and film principle, which extensive experience has proved gives the best results. The distributing troughs and gutters are of the open top type, thus allowing the quick removal of solids and foreign matter which invariably accumulate, due to the continuous process of evaporation. The distributing tubes are of 'Venturi' type made of acid-resisting earthenware, as also are the splash plates. The water is thoroughly atomised before falling into the irrigation or lath system. The laths are fixed without the use of nails, being held in place in machined-notched bearers. The design provides for keeping the air in contact as long as possible, whilst allowing the maximum amount of air to be circulated through the plant.

The Open type construction, such as is usually employed for dealing with the jacket water for internal combustion engines, is constructed on somewhat similar lines, but the outside faces are louvred to prevent splashing out. Since this type of tower is not fitted with a chimney, the air circulation is much slower, and consequently the space occupied for a given duty is much more than with the natural draught Chimney type construction. In cases where the water volume is comparatively small, and it is desired to reduce the temperature to a very low degree, this type of cooler is especially suitable.

Forced draught.—Where the space available is limited, Forced Draught Towers can be supplied but they are uneconomical from the point of view of running cost, as compared with Natural Draught Plant as power must be provided to drive one or more fans, but it is the most flexible type as the air supply is positive and under control. Where space is very restricted or low re-cooled temperatures essential the forced draught tower is the only solution. It may be constructed of timber, steel, or concrete and for indoor installation 'Premier' steel cased 'Mechanical' coolers, or shell and tube heat exchangers are available.

Airblast coolers.—These are of the motor car radiator type fitted with gilled tubes through which the liquid to be cooled is circulated and over which air is forced by a fan, or fans. These can be used as air coolers by inversion.

The Premier Cooler Co. also manufactures air washers, dry cloth pocket and adhesic air filters and oil separators.

WATER AND OIL COOLERS.

(Visco Engineering Co., Ltd., Croydon.)

Water cooling plants utilising the principle of evaporative cooling are essential in many industries although the performance of such coolers is governed by the atmospheric wet bulb temperature which is the physical limit to which water can be cooled by this method. In practice, how-

ever, it is only commercially practicable to cool to within a few degrees of the wet bulb temperature.

The Visco Engineering Co., Ltd., of Croydon, has had many years experience of the design and construction of coolers of all types and sizes in many different parts of the world.

The most usual type of plant for dealing with large quantities of water as in power station work, is the natural draught chimney type cooling tower, in which the draught is caused by the temperature differential and the chimney effect of the cooler shell. In these towers, the outer shell or 'chimney' may be constructed of suitable timber braced and strengthened to resist any wind pressure likely to be brought to bear on it, or of ferro-concrete.

The lower part of the cooling tower contains the water distribution and cooling hurdles, and the upper part forms the chimney of sufficient height to create the necessary draught.

The hot water delivery pipe is connected to main distributing troughs from which the water flows into the distributing gutters placed at right angles. The gutters are so arranged that all receive an approximately equal quantity of water without swilling. The bottom of the gutters is fitted with glazed china nozzles through which the water falls in firm jets on the glazed china circular splash plates, which throw it in an upward and outward direction, forming an umbrella-shaped cone. The splash plates are so spaced that the whole area of cooling stack is covered equally by the falling spray.

The cooling hurdles and the water distribution are carried by a substantial framework independently of the tower itself. The posts of the framework rest on the concrete piers of the foundation. The cooling hurdles consist of substantial triangular laths cut diagonally out of square timber, and laid horizontally into notched bearers, which in turn, are carried by the posts of the framework. No nails are used for fixing the rails or bearers, as they would be liable to corrosion from the damp air.

For somewhat smaller installations an Open Type Natural Draught Cooler can be utilised to advantage.

To all intents and purposes the open type cooler consists of a chimney cooler without the chimney itself. This type of cooler is dependent on natural air currents, and is so designed that wind currents can pass straight through it. A properly designed cooler of this type will function satisfactorily with air currents as low as 3 miles per hour. Such towers are very inexpensive to maintain, and running costs are limited to the cost of pumping. They are of timber construction and may be mounted on a steel supporting structure or installed at ground level with a concrete sump. Open type cooling towers are provided externally with louvre boards which prevent loss of water due to windage.

Where cooling conditions are most stringent and space and site limitations preclude the installation of a natural draught cooler, forced draught is necessary. This is usually provided by fans either directly or indirectly driven by weather-proof electric motors. In cold weather, and when full load is not required, one or more of the fans can sometimes be stopped and the cooling obtained by natural draught with a corresponding saving in power.

Where space is plentiful, particularly where large ponds already exist, spray coolers can be used to advantage. These consist of a system of cast iron pipes projecting the water to be cooled through gun metal nozzles upwards to the atmosphere in finely divided form. When correctly dimensioned, they give efficient service, where the cooling conditions are not very stringent.

In cases in which it is necessary to cool small or medium quantities of water for Diesel engines, air compressors, degreasing plants, refrigerating plant condensors, etc., a mechanical cooler, such as the Visco 'Steelshell Forcedraft' cooling unit will be found very satisfactory. A cooling unit of this type is independent of natural air currents and can be installed indoors or outdoors. It is also so compact that it can often be placed in an odd corner which cannot be utilised for any other purpose. The installation of such a cooler will often save over 90 per cent. of water which would otherwise be wasted.

These steel shell coolers are sometimes of the induced draught type with the fans at the top. With this design, air inlets are at the base of the cooler shell on all four sides. Very good air distribution is thus obtained. Other advantages are that the cooler is perfectly symmetrical thus occupying less space, and the height of the water inlets is reduced with consequent saving in pumping costs.

Oil Coolers.—The Visco 'Sprayblast' Oil Cooler (Patent No. 531052) was designed to meet the needs of heat treatment plants for an efficient method of cooling oil for both batch quenching and continuous quenching.

The main principle of the design is the full use of the latent heat exchange caused by the evaporation of a small quantity of water in addition to the normal heat exchange between the air and the oil.

Cooling is effected by passing the oil through copper tubes on the outside of which cold water is sprayed, the cooling action of the spray being assisted by a continuous blast of air directed downwards over the cooling tubes.

As there is no contact between the oil and the cooling medium, the characteristics of the oil are not impaired by oxidation.

The amount of water lost by evaporation is relatively small, and amounts in practice to approximately 50 gallons per hour per ton of steel quenched per hour.

Coolers of this design are also being used successfully with oil cooled transformers and for other similar purposes.

SECTION XXVIII

Internal Combustion Engines.

THE BROTHERHOOD-RICARDO ENGINE.

(*Peter Brotherhood, Ltd., Peterborough.*)

The Brotherhood-Ricardo Engine (p. 1267) was first produced on a commercial basis in 1928 after many years' experimental work. It was the first high speed engine, using heavy oil as fuel, in which the inlet and exhaust valves of engines of the usual four-cycle type are replaced by a single sleeve surrounding the piston.

The operation of the sleeve is as follows :—

Air inlet and exhaust ports are formed on opposite sides of each cylinder and are opened and closed by corresponding ports in the sleeve. This sleeve is driven by a ball socket bearing on a rocker beam to which motion is imparted by a crank pin on a half speed shaft working on the centre bearing of the beam, the other end being coupled to a fulcrum link fixed to the crankcase.

This mechanism makes the sleeve move over a path approximately elliptic, with the minor axis vertical. In consequence, the change in velocity, and therefore the forces due to inertia are extremely small.

Another leading feature of the design is the system of fuel injection.

The rapid intermixing of the particles of the fuel with the air needed for quick and complete combustion is not, as in most engines, achieved by injecting the oil in a fine spray, but by relying on the turbulence of the air compressed in the cylinder. This state of violent turbulence is caused by tangential arrangement of the air inlet ports, and the acceleration of the initial swirl of the air as it is trapped in the combustion space. The fuel is injected where the speed of the air is greatest, *i.e.* at the side of the combustion space and complete mixing of air and fuel results.

In other respects such as forced lubrication, oil cooling, etc., the design follows modern high speed engine practice, except that the crankshaft is built up with case hardened and ground journals and floating bushes on the crankpin journals.

The engines are made with two standard sizes of cylinder, 44/50 B.H.P. at 750/900 r.p.m. and 63 B.H.P. at 800 r.p.m., so that combinations of from 4 to 8 cylinders cover all powers between 200 and 500 B.H.P.

The fuel consumption at full load ranges, according to the size and power of the engines from 0·36 to 0·42 lb. per B.H.P. hour.

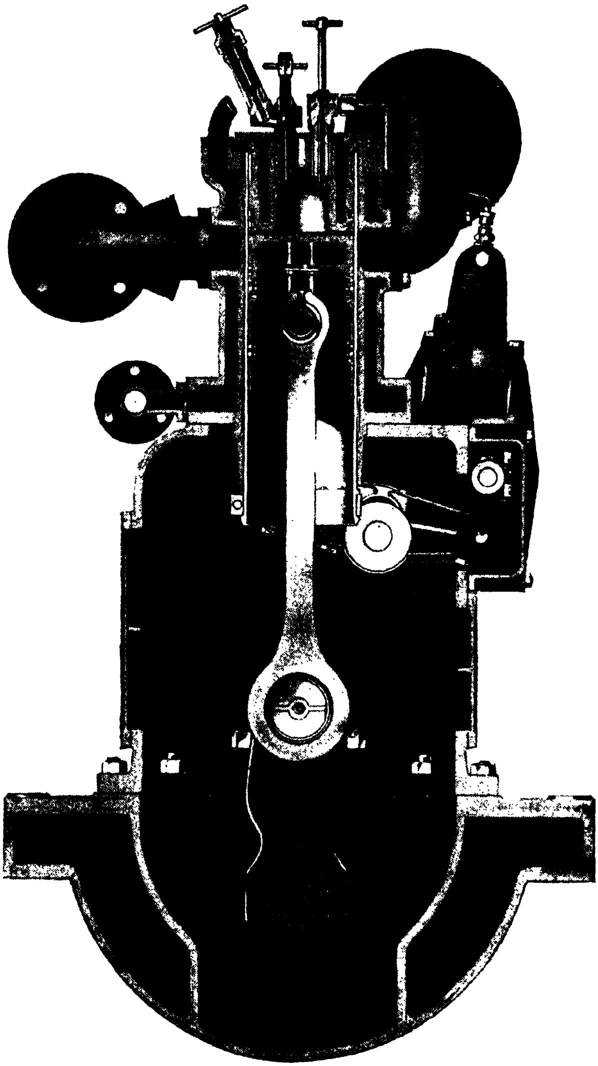
THE GLENIFFER MARINE DIESEL.

(*Gleniffer Engines, Ltd., Anniesland, Glasgow.*)

The Gleniffer heavy-oil engine is designed specifically for marine propulsion and is made in the D.C. series in units of 3, 4, 6, and 8 cylinders, developing 20 b.h.p. per cylinder continuously at 900 r.p.m. In the D.B. series it is made in units of 2, 3, 4 and 6 cylinders developing 12 b.h.p. per cylinder continuously at 1,000 r.p.m. As will be seen from the cross section of the D.C. engine (the D.B. being of somewhat similar design) the valves are placed horizontally facing each other in the cylinder head and are opened by the camshaft through levers and pull rods for the admission valves and direct through levers for the exhaust valves. The engine is of the solid injection type having the sprayer central over the top of the combustion chamber proper.

A projection on the top of the piston increases the turbulence at the top of the stroke by entering a restricted passage in the head. The makers guarantee a consumption of fuel oil not exceeding 0·44 lb. per b.h.p. per hour. Starting is effected by means of a compressed air motor which is mounted over the flywheel and engages through a self-disengaging pinion with a gear ring on the flywheel. In the case of the D.B. series the air motor is of the V-type and is carried in a cradle which can, if required, take a 6-in. electric starter. As soon as the engine is started the air motor automatically disengages.

The manufacturers claim that with their air motor up to thirty starts can be obtained from a 3½ cub. ft. air receiver without recharging, and this includes the first start from stone cold. Compressed air up to 300 lb. per sq. in. is obtained by employing one of the main engine cylinders as



Brotherhood-Ricardo Engine.

a pure air compressor, whilst its fuel pump is cut out of action. It is also claimed that these engines can be slowed down to well under 200 r.p.m. at which speed they will continue to operate in a most satisfactory manner, accepting ahead or astern gears without protest.

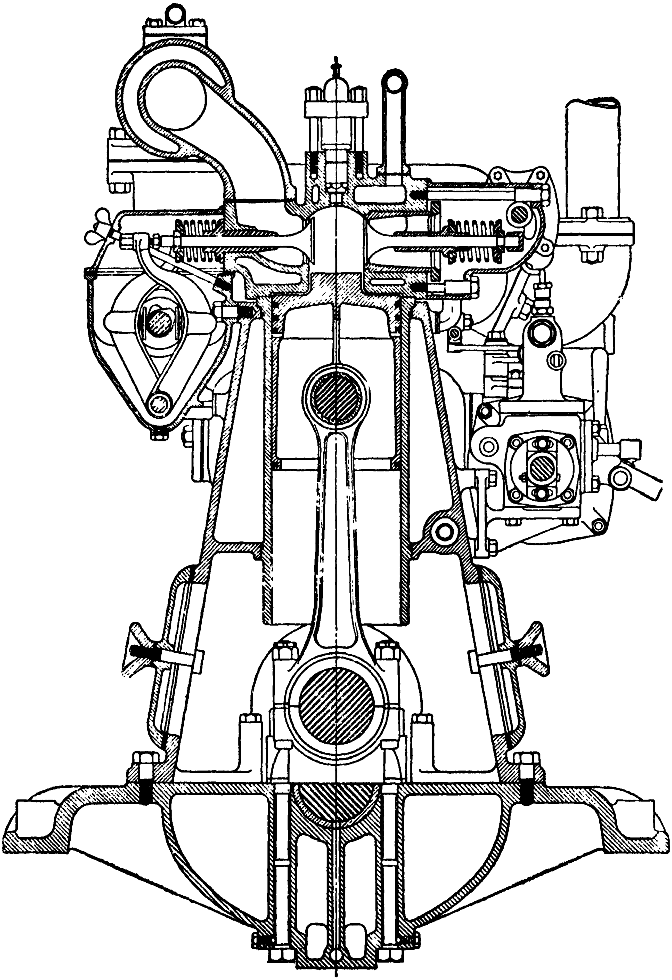


FIG. 1.—The Gleniffer Heavy-Oil Engine.

The lubrication system is of the force-fed type to the main and big end bearings and gudgeon pins, all the passages being drilled, with no internal pipes inside the crankcase. The force and scavenge pumps are of the valveless oscillating cylinder type and maintain a dry sump. They respectively suck from and deliver the oil to an oil reservoir fitted with a dip stick and large filler cap, and a small gauge shows the pressure to the bearings. The delivery pipe from the reservoir

passes through an annular passage in the water jacket, thereby ensuring sufficient cooling in the hottest of climates.

In the case of the D.B. engines the scavenge pump and the cooler are omitted, the pump being submerged in the sump.

Being designed wholly for marine propulsion all Gleniffer engines are equipped with full thermostatic control of the temperature of cylinder walls and heads. Without modifications of any kind they can be used in Arctic or tropical waters. Marine reverse gears, of the bevel epicyclic type, having a very large margin of safety and requiring no adjustment for several thousands of operating hours, are fitted to all models and specially developed marine governors are employed to ensure complete ease of operation and steady running under all conditions of speed, load and weather.

In addition to these engines the firm also manufacture a twelve-cylinder and a sixteen-cylinder V engine of 240 b.h.p. and 320 b.h.p. continuously at 900 r.p.m. These engines are a natural development of the D.C. series, and have many of the parts strictly interchangeable with this group of engines.

Engines of 16 cylinder 320 b.h.p. size have been built and supplied for patrol boat work, with superchargers driven from the engine units, and the output including the power absorbed for the superchargers is 420 b.h.p. at 1,000 r.p.m. The superchargers are so arranged that the engines can be run either as ordinary straight-forward units or by clutching in the superchargers to give the power stated above.

Bibby Couplings.

(*The Wellman Bibby Co., Ltd., Artillery House, Artillery Row, London, S.W.1.*)

As shown by the accompanying engraving (fig. 1), the Bibby coupling comprises two discs, each provided with teeth and coupled together by a continuous spring threaded between the teeth in a serpentine manner. The spaces between the teeth are flared, and the spring fits them

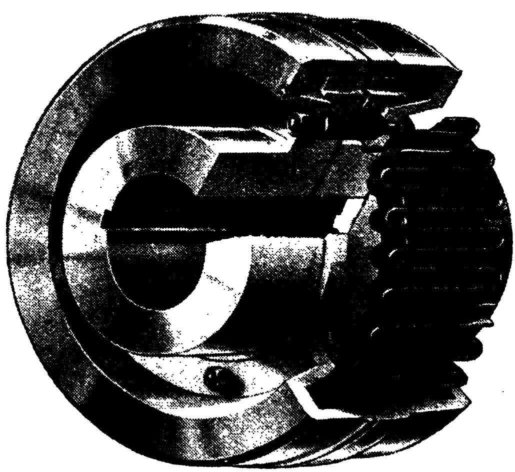

FIG. 1.

freely to allow of the desired movement. One of the discs is, of course, keyed to the driven and the other to the driving shaft.

The Bibby coupling was the original coupling having flared teeth connected by plate springs. The separate plate system was discarded on account of its low resiliency efficiency, due to its acting as a double cantilever. The efficiency of any cantilever spring is only 33 per cent.

Now consider one element, AB in fig. 2 in the Bibby Continuous Grid Spring transmitting a load P from a driving to a driven tooth. The reactions from the teeth P and P form a left-hand

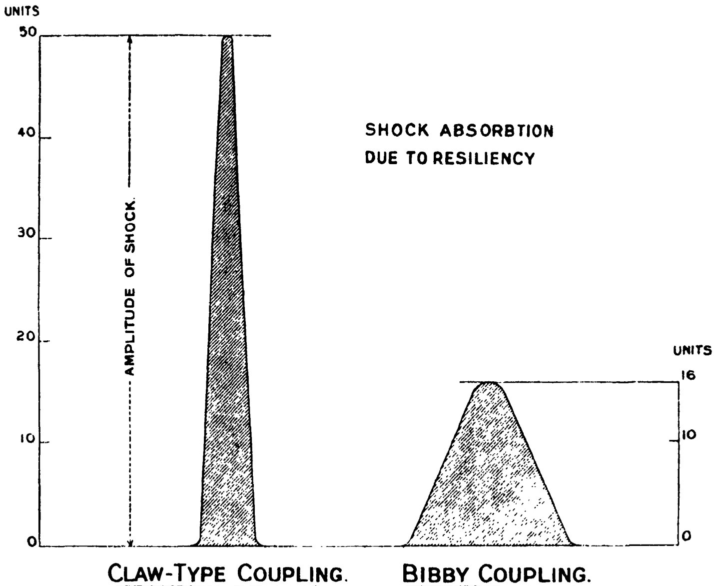
FIG. 3.

couple, P × s, in the spring element. For equilibrium this must be balanced by a right-hand couple. The other external forces on the element are its connections at the middle of the bends, A and B, to the adjacent elements and consist of forces T and T forming a couple T × p, which is equal and opposite to P × s. The forces T on the element must act inward since the couple is right hand.

For the next element, CD, we have the same left-hand couple from the teeth loads, which are again balanced by a right-hand couple. For this element the bends are turned in the opposite directions, so that the forces T_1 and T_1 at C and D act outwards, giving the right-hand couple.

Where the two bends meet at BC there is an inward force T and an outward force T_1, which are equal and opposite and cancel each other. There are, therefore, no external forces on the spring except the useful normal ones at the teeth.



VIBROGRAPHS TAKEN BEFORE & AFTER FITTING BIBBY COUPLING.

UNDER EXACTLY SIMILAR DUTY.

FIG. 4.

Along the straight outside portions of the spring, KM for instance, the bending moment is Tp/2, and is constant. As the points of contact K and K between the spring and teeth approach each other, the length KM becomes longer, until, finally, almost the whole of the spring is under a constant bending moment and, therefore, has an efficiency of nearly 100 per cent. instead of the possible 33 per cent. with the cantilever types.

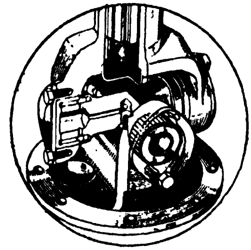
This property of high resiliency has a marked effect on every kind of drive. Fig. 3 shows a typical Diesel torque diagram, taken before and after fitting a Bibby coupling. The coupling stiffness is adjusted to take the criticals away from the running speed, and a special damping factor is introduced to detune the criticals. Fig. 4 shows the shock diagram taken from a 40,000 h.p. rolling mill.

Needle Bearing Propeller Shafts and Universal Joints.

(Hardy Spicer & Co., Ltd., Birch Road, Witton, Birmingham, 6.)

The original universal joint, or 'Hook's Coupling,' consisted of a cross and two yokes. Either yoke could be swung about the arms of the cross to which it was connected, and as the two arms lay at right angles it was possible to move the shafts in any direction.

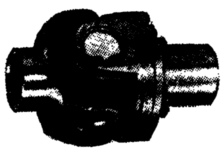
The latest Hardy Spicer needle bearing joint consists of two one-piece forged steel yokes and a single forged steel trunnion cross with the addition of four needle bearing assemblies. The needle bearings which fit into the yoke holes are self-contained, the needle rollers being assembled in a hardened steel retaining cup. In light duty types the needle bearing assembly is a light press fit, held in place by a lock spring, while in the heavy duty models the assembly is inserted in the yoke holes over the trunnion cross and is held by a retaining plate and cap screws.



Sectional Drawing showing Needle Bearings.

Hardy Spicer Needle Bearing Universal Joints are manufactured in two different types. The Standard, operating at angles up to 22°, is available in all sizes covering the entire field of light and heavy duty work. The Wide Angle operates at maximum angles from 30° to 35° and is designed for heavy duty service.

Standard Joints.



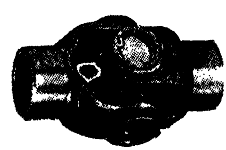
Standard Joint.

The simplicity of construction in accurately and securely retaining the needle bearings in proper position is shown in the above illustration.

The rigidity of the integral yoke lugs, which is not affected by bolt fastenings of any kind, reduces to a minimum objectionable torsional deflection, and the shaft assembly as a whole is right in weight and practically frictionless in operation; the tunnion cross on these models is provided with a large oil reservoir in each end.

Wide Angle Joints.

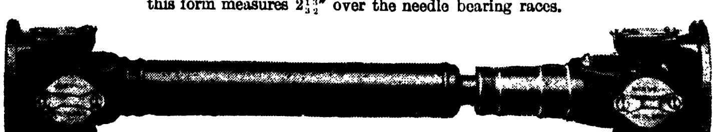
The wide angle universal joints have been designed to accommodate the extreme angular action required in many present-day specialised vehicles where dual axle drive (six-wheel construction) is used, and will give satisfactory and trouble-free operation at running angles from 30° to 35° each way. These wide angle joints are of the same construction and material as the standard needle bearing assembles with the exception that special yokes are incorporated in the design to provide the extreme angles required in an installation of this kind.



Wide Angle Joint.

Purposes.

Quite apart from automobile usage the Hardy Spicer universal joint has very wide and increasing engineering applications in the driving of machine tools, in accessory drives and power take-offs, in operating remote controls and generally in any situation where angular control or drive is needed. The smallest assembly available in this form measures 2$\frac{3}{32}$" over the needle bearing races.



Hardy Spicer Universal Joints and Propeller Shaft Assembly.

Water Coolers.

(*Heenan and Froude, Ltd., Worcester, England.*

The P type cooler manufactured by this firm has the advantage of being compact and occupying comparatively small space. The apparatus is self-contained, and has no moving parts except the fan which circulates the air, and the pump which circulates the water. The cooler is constructed entirely of metal.

The cooler consists of an outer casing, which is rectangular in shape, built up of thick mild steel plates. The base of this casing forms a tank into which the water drains after cooling, previous to re-circulation.

The water to be cooled, after passing through a strainer, enters at the top of the cooler and percolates through screens. In its fall it comes into intimate contact with a current of cold air which is forced upwardly through the casing by a high-efficiency axial flow fan, the discharge from which is introduced to the underside of the lowest screen.

The screens are formed of metal and provide a very large area for the interchange of heat; large access doors are provided through which the screens can be withdrawn for inspection.

The cooling effect is positive and continuous, the volume of air being a predetermined quantity which is not dependent on climatic conditions.

As the cooler makes use of the principle of evaporation it provides cooled water at a temperature which is frequently below that of the prevailing atmospheric dry bulb temperature; it is widely employed for re-cooling the jacket water of Diesel and other internal combustion engines, refrigerating condensers, air compressors, etc., and saves at least 95 per cent. of the water otherwise wasted. The power absorbed by the fan is usually only a very small proportion of the power of the engine with which the cooler is dealing, and it is often possible to supply the cooler with air drawn in from the engine room, thus assisting in the ventilation of the latter. The cooler can, in fact, be installed in the engine-room itself, thus simplifying the piping system and rendering the engine house almost independent of outside sources of water supply.

SECTION XXX

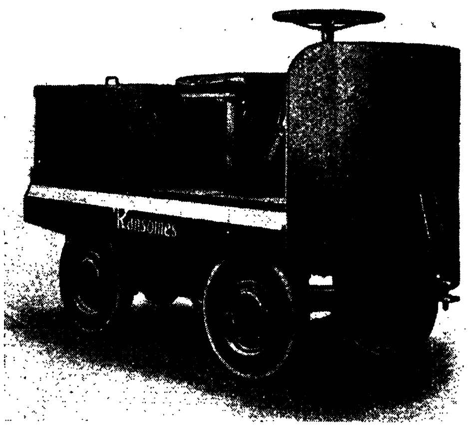
Automobiles.

Electric Industrial Trucks.

(*Ransomes, Sims & Jefferies, Ltd., Ipswich.*)

In present-day manufacturing conditions where efficiency in production is of the utmost importance, handling of goods and materials is a vital factor. In the majority of cases, the modern electric truck, by virtue of its low running and maintenance costs and length of life, constitutes the most economical goods-handling unit it is possible to employ.

It is no exaggeration to say that, as compared with hand trucking, an electric truck will in many cases treble the work performed at one-eighth the labour cost.



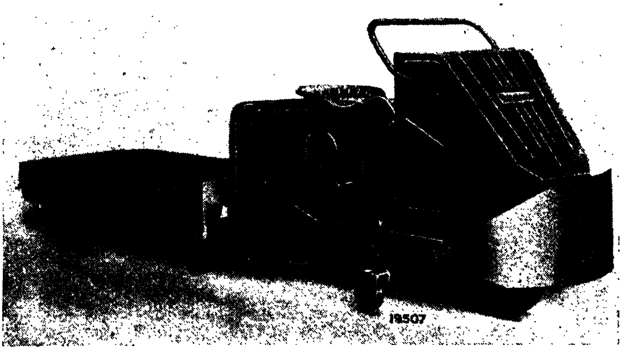
Electric Tractor, Type T.3 for hauling loads up to 6 tons.

Ransomes, Sims & Jefferies, Ltd., of Ipswich, were the first British makers of battery-driven electric trucks, and to-day they offer a wide variety of types. A model in great demand is the 2-ton truck with elevating platform. This truck may have either 2- or 4-wheel steering and carries its 2-ton load at a speed of 4–5 m.p.h. It is capable of ascending a 1 in 5 gradient. The drive is by means of double reduction spur and helical gear totally enclosed and running in oil, a 4-pinion differential is incorporated, and the shafts drive the wheels through universal ball joints. The drum type controller operated by foot-pedal gives four speeds forward and reverse and is interlocked so as to prevent simultaneous application of power and braking. The reverser is hand operated. The platform is elevated electrically by operating a lever conveniently placed for the driver's hand.

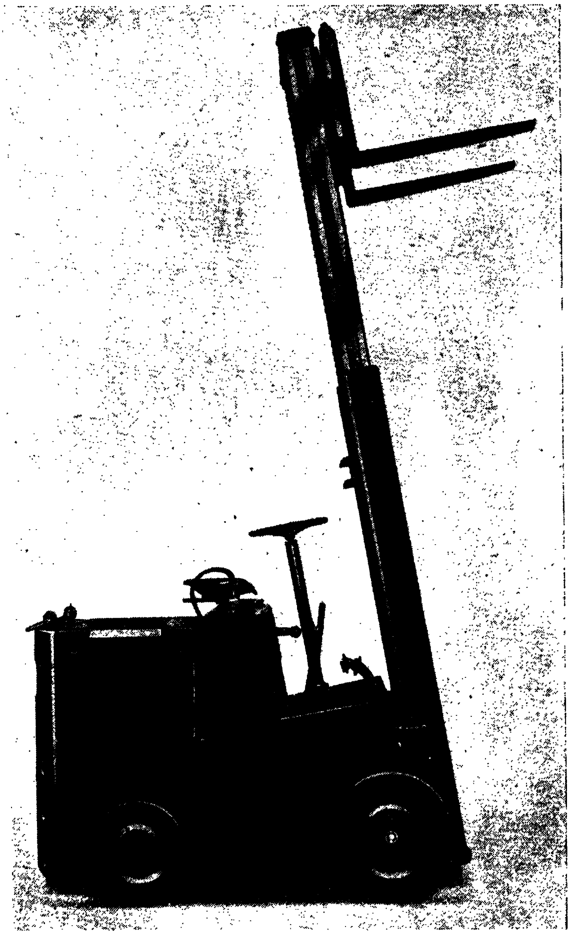
The 2-ton trucks can be supplied with high or low platforms and there is a similar model with a smaller platform particularly suitable for heavy loads and for operating in narrow gangways. The elevating trucks are, of course, intended for use with stillages which are loaded as required and left for the truck to collect when it comes along. The stillage is picked up in a few seconds and is deposited at its destination just as quickly. In some cases, however, it is preferred to place the load direct on the truck platform, and to meet such requirements similar trucks without the elevating gear can be supplied.

Ransomes' 1-ton capacity trucks are available in various models, with or without elevating gear, and with platforms high or low, wide or narrow, long or short. The driving unit is self-contained and mounted on a turntable, the drive being by double reduction roller chain from the motor to the driving wheel. Steering is effected by turning the whole of the driving unit by means of the control rail.

Electric Crane Truck—lifts 10 cwts.—transports 30 cwts.

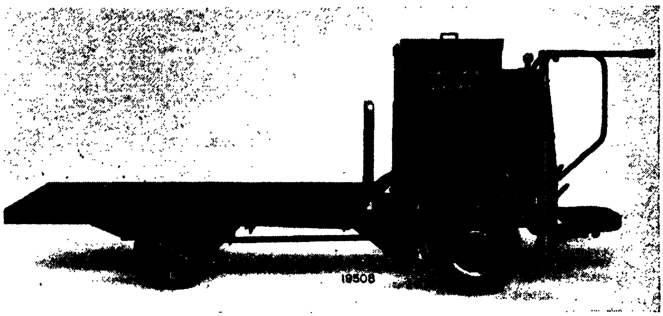


1-ton Electric Truck with low elevating platform.



' Fork-lift 20 ' Electric Fork Truck.

Ransomes' latest production is the Forklift 20, which is a battery-driven electric fork truck for loads up to 1 ton. The maximum height of lift is 10 ft. and the hoisting speed 22 ft. per minute. Special features are the compact design, small turning radius, and telescopic lifting gear which enables the truck to pass through doorways and girders, while still allowing for stacking between



2-ton Electric Truck with high elevating platform.

the girders. The mast tilts forward or backward, and the forks are adjustable laterally to suit different sizes of loads or pallets.

For heavier work there is the 'H' type truck which will deal with loads up to 4 tons, and in addition, the firm offers various other types including tipping trucks, crane trucks, and tiering trucks, among the latter being special models for handling loads of tin plate and other sheet metal. Other Ransomes battery-driven products include stackers, tractors, and run-about cranes.

Motor Lawn Mowers.

(Ransomes, Sims & Jefferies, Ltd., Ipswich.)

More than 100 years ago—in 1832—Ransomes made the first lawn mower (Budding's patent) while 70 years later they produced the first petrol-driven motor lawn mower. Today the range of Ransomes' motor lawn mowers covers every possible condition for which a power driven machine could be required.

The standard machines with air-cooled engines range from 14 ins. to 36 ins. in width, while for large flat areas, up to about 12 acres, there is the 40-in. combined motor mower and roller with water-cooled engine and with seat for the operator.

Exceptional care has been taken to ensure efficiency, simplicity, and economy in running. All engines conform to the most modern motor practice and are specially designed so that effective power is obtained at medium speed. Self-aligning ball bearings are fitted wherever advisable, and the maximum protection is given to transmission and driving mechanism. All controls in the air-cooled models are operated from the handles, while to facilitate turning the land rollers are made in sections. In the water-cooled machine the driver has complete control from the seat, and, moreover, can empty the grass-box without dismounting. In all sizes the cutting cylinder can be put out of gear and the machine used for rolling only.

A very interesting feature of the latest machines is the self-energising automatic switch, which makes these machines particularly easy to control.

To illustrate the saving in time which can be effected, and the low cost of running, it may be mentioned that the 30-in. model will cut up to an acre in an hour with a petrol consumption of less than 2 pints.

In addition to being first in the field with hand and petrol lawn mowers, Ransomes were the pioneers in this country of the electric lawn mower. In these machines an electric motor takes the current through a flexible cable from some convenient point, so that the mowers are particularly suitable for compact lawns where the supply is easily accessible. The motors can be supplied for alternating or direct current and are of Ransomes' own manufacture, specially designed for the purpose. A feature of these machines is that the absence of vibration ensures a particularly smooth even cut.

SECTION XXXII

PART II

Locomotives and Rolling Stock.

THE 'MELESCO' SUPERHEATER.

(The Superheater Company, Limited, London and Manchester.)

The headers or collectors of this apparatus are situated in the smoke-box and are all made of 'Melescoloy' a special semi-steel mixture, giving a tensile strength of not less than 28,000 lb. per sq. in.

The elements shown in fig. 1 are of double loop type, giving a four-fold steam path; they are made from solid cold-drawn steel tubing, and the three return bends on each element are formed by the 'MELESCO' Integral Machine Forged Return Bend Process, by which these bends are made integral with the tubing itself, and all electric and oxy-acetylene welding eliminated, thereby prolonging the life of the element and ensuring a clean, smooth finish both internally and externally.

Where elements are supplied having the ball joint attachment, fig. 2, the ball end is also made integral with the tube itself by upsetting the tube, thus avoiding any welding. It is afterwards turned and ground to gauge, having a diameter of 2¼ ins.

Where bolts are required for the joint, these are supplied in high tensile steel having a tensile strength of not less than 50 tons per sq. in. with a yield point of 35 tons per sq. in., so preventing the possibility of stretching when screwing up.

Other details, such as clamps and washers, are all made from drop forgings, which ensures sound material and maximum strength.

All elements are fitted with one or more steel bands and supports of robust construction, so arranged on the elements that the latter are properly positioned in the flue tube and at the same time reducing the obstruction to the flow of the gases to a minimum.

THROUGH BOLT HEADER, TYPE 'A.M.'

In this design of header, fig. 3, the casting is divided into transverse compartments or pockets communicating alternately with the saturated and superheated steam passages which are situated longitudinally at the back and front of the header respectively. Air passages which act as insulating spaces between these compartments are utilised for housing the element clamp bolts, the 'T' heads of which lie in a horizontal plane above the header, the nuts being below, or if desired the bolts may be used with their heads bearing upon the element clamp and the nuts on the top of the header. The ball joint attachment is universally fitted with this type of header, and is shown in fig. 3. As will be seen, any element can be easily withdrawn without removing the bolt.

'STIRLING' THROUGH BOLT HEADER, TYPE 'A.S.'

This header, fig. 4, has similar insulating passages between the compartments or pockets In this case, however, the saturated and superheated passages are arranged one above the other at the back of the header with communicating compartments or pockets at right angles. The slots or insulating passages, in addition to allowing for independent expansion of the compartment walls, are utilised for housing the clamp bolts with nuts either on top of the pockets or below the clamps as desired. It will be observed that to withdraw the element it is merely necessary to slacken the nuts, after which the bolt will slide out of the insulating space as the element is withdrawn, without having to remove the bolt from the clamp.

THE 'MELESCO' SUPERHEATER.

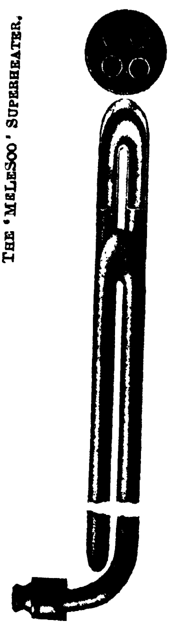


FIG. 1.—'MELESCO' Ball Joint Element.

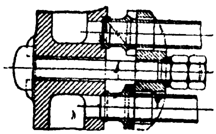

FIG. 2.—'MELESCO' Ball Joint.

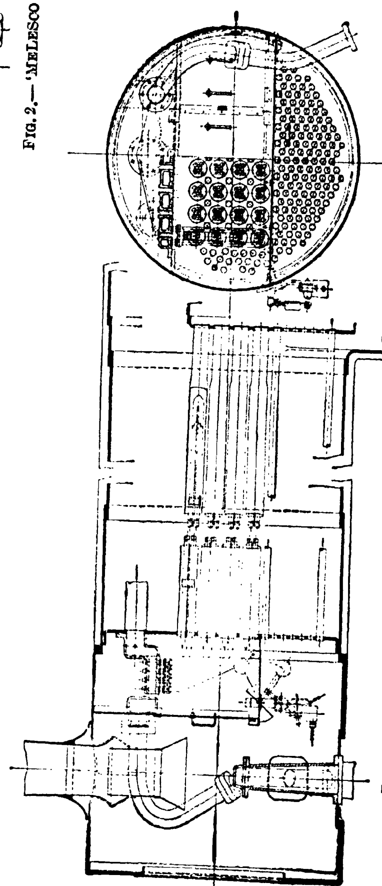

FIG. 3—'MELESCO' Through Bolt Herder, Type 'AM.,' with Ball Joint Attachment.

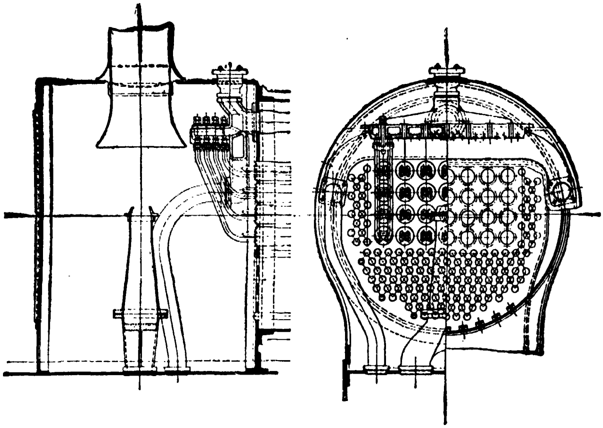

FIG. 4.—'Stirling' Through Bolt Header, Type 'A.S.'

MULTIPLE VALVE REGULATOR HEADER, TYPE 'AXV.'

With the advent of higher steam pressures and larger boilers, consequent on the increased size of locomotives, the combined superheater header with Multiple Valve Regulator as shown in fig. 5 has become a necessity.

This apparatus consists of Through Bolt Type Header, with which is cast integrally a chamber for housing the regulator valves and cam shaft.

The valves, which are of comparatively small diameter and therefore not liable to distortion, are operated by this cam shaft and closing affected by positive mechanical action of the cams.

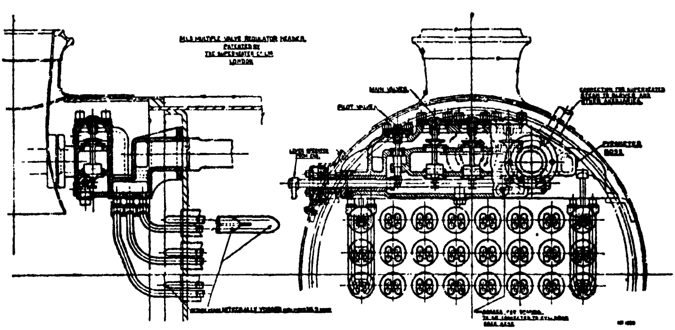

FIG. 5.—Multiple Valve Regulator Header, Type 'AXV.'

The valves are so nearly balanced that only a minimum amount of effort is needed to move them. This balancing is accomplished by providing a small pilot valve which opens first admitting steam to the balancing chamber preliminary to opening the main valves. The main valves are designed to open so that the passage of steam through the superheater and regulator is uniform providing a perfect graduation in the supply of steam to the locomotive cylinders.

In other respects the apparatus is similar to the usual designs and Ball Joint Elements are fitted. Large numbers of this type of header are now in service on railways throughout the world.

UNITED KINGDOM METALLIC PACKING.

(*Locomotive Packing cast-iron type.*)

(*The United Kingdom Self-Adjusting Anti-Friction Metallic Packing Syndicate, Ltd., Fazakerley, Liverpool,* 9.)

This type of packing has been specially designed to meet the requirements of consulting engineers and locomotive builders who are now favouring cast-iron blocks for packing to work against the present-day high degree of superheat.

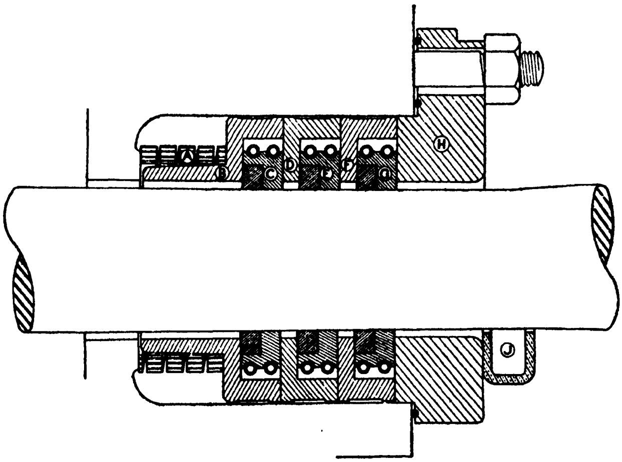

FIG. 1.

Its simplicity will be obvious from an examination of the illustration, fig. 1.

The covers B, D, F, containing the wearing blocks C, E, G, are held in position by a powerfu spring A, which adjusts the packing and tends to take up the wear on the walls of the covers (see fig. 1). When wear does take place, the covers themselves require only a slight adjustment by refacing, and can be replaced at a very low cost as against the entire replacement of the expensive housing made in halves, a prominent feature in the old German design of cast-iron packing.

The withdrawal of the packing is greatly simplified as, on the release of the gland H, the spring forces the packing from the stuffing box.

These packings are made from the highest quality of cast iron obtainable, and the best workmanship is used in their manufacture.

Lubrication arrangements can be provided as part of the gland, or separately.

One of the leading British Railways to which this packing has been supplied gave the official mileage covering a period of 5 years without renewals at 289,000. On dismantling the engine for general repairs, the internal covers B, D, F, and bearing rings C, E, G, were found to be in good condition. After regrinding the steam faces of the covers, together with the necessary adjustment to the cuts in the bearing rings, the complete packing was put back for further service and has since done well over 100,000 miles.

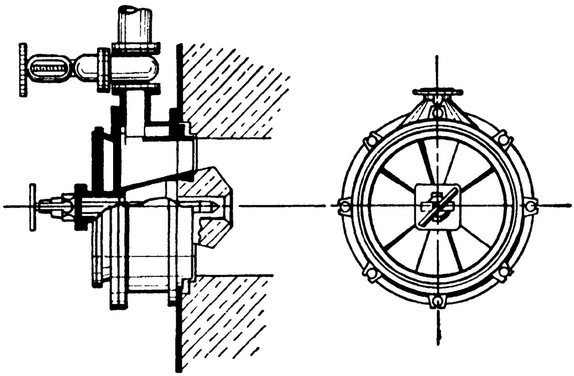
SECTION XXXIV

PART I

Heating.

THE 'GAKO' GAS BURNER.

(*Liptak Furnace Arches, Ltd.*, 68 *Victoria Street, London, S.W.* 1.)



The principle of the 'Gako' gas burner is the introduction of the gas and air in separate streams, to which is imparted a whirling motion. The resultant intensive mixing produces practically complete combustion. There are no moving parts, and the capacity range is wide without fear of back-firing. The gas consumption is claimed to be very low and the efficiency high.

The illustration shows a standard oil burner inserted through the centre for auxiliary firing.

SECTION XXXIV

PART II

Ventilation—Air Filtering.

VISCO AIR FILTER.

(*The Visco Engineering Co., Ltd., Stafford Road, Croydon.*)

The Visco Air Filter (devised in 1916) is used in conjunction with turbo alternators, pipe ventilated motors, and general ventilating plants. It works on the principle that the air volume is divided into a large number of thin streams which are passed through a layer of specially prepared filter bodies, the surfaces placed irregularly to each other, so that the direction of the air flow is changed suddenly and a great number of times. The filter bodies are thin copper-plated steel rings $\frac{7}{16}$ in. diameter and $\frac{7}{16}$ in. long, coated with a thin film of Viscinol, which is a specially prepared blend of highly viscous mineral oils. When the direction of the air flow is changed, the dust particles continue in the original direction and are thrown against and retained by the Viscinol-coated surfaces.

The filter is standardised in units 20 by 20 ins. square and 3 ins. deep, consisting of frame and cell, which latter is simply clipped on the frame. The capacity per unit is 600/700 c.f.m. Pressure loss is practically steady at 0·25 in. water gauge. Average consumption of oil, 1 gallon per unit per annum. Cleaning is done by rinsing in hot soda water on the average every eight weeks, depending on the original dust content and length of daily run. There are practically no other running costs.

The filter units are assembled in a convenient shape to make up any capacity, and are preferably built into the alternator foundations (thus taking up no valuable space) or as self-contained units in any position.

The *advantages* claimed are: No moving or wearing parts, all metal, fireproof, foolproof, small space.

The Visco Duplex Filter has two cells in series, the primary of standard construction and the secondary filled with smaller size filter rings. This type has an extremely high efficiency and is for ordinary purposes, coated with Viscinol, but for hospitals and food factories, with Stericidol, a stable copper-glycerine solution for not only filtering, but at the same time removing and destroying bacteria.

In the Visco Patent Self-Cleaning Air Filter sinuous metal plates are used as the filtering medium. These are contained in rectangular cells which are arranged in vertical columns. By suitable gearing the bottom cell is lowered with a swinging motion into a bath of oil in such a way that a vigorous rinsing action takes place. At the same time, another cell from the previous operation, in draining position behind the column, is moved upwards to the top of the column. Where the dust loading is exceptionally heavy, instead of using an oil bath, sprays can be fitted which subject the cell to pressure oil spraying from both top and side which removes all the accumulated dust.

The Visco 'O.E.' Filter with 'throw-away' filter element is designed for use when a filter of **the non-viscous type is required.**

Dust Collection.

'VISCO-BETH' DUST COLLECTORS.

(The Visco Engineering Co., Ltd., Stafford Road, Croydon.)

This fully automatic Dust Collector is used for collection of almost any kind of material in powder or fibrous form, such as flour, coal, cement, lime, tobacco, flue ashes, sugar, soap, milk sulphur, ores, enamels, chemicals, metallic dusts and metallic fumes, in connection with pulverising, drying, calcining, hydrating, conveying and other plants.

With the 'Visco-Beth,' which operates under suction, the air or gas is drawn by main fan through a number of cloth tubes, on which the dust entrained in the air is retained whilst the cleaned air (to exhauster) is discharged to atmosphere.

The tubes are made of wool, cotton or other material suitable for particular working conditions. They are arranged in compartments of 9, 12, 15 or more with, usually, a diameter of 6 ins. or 8 ins. and a length of from 7 ft. to 10 ft.

The unit comprises a number of compartments, each of which is, in rotation, isolated by the mechanical closing of independent air valve. During this period the tubes are automatically shaken a number of times and a current of clean air (scavenging) is permitted to flow through the filtering media in an opposite direction to that taken by the normal air stream. The scavenging air is, as a rule, controlled by separate fan, and pre-heated in cases where the dust-carrying air is highly charged with moisture, thus preventing condensation in the casing and wetting of cloth.

All valves and gearing are mounted on a top plate and operated by separate motor or from the shaft of the main or scavenging fan. Below the filter casing is a hopper for collecting the recovered material with conveying spiral to discharge the dust through a star type rotary valve.

This Dust Collector is entirely automatic in action, and the regular cleaning keeps the filtering efficiency constant at over 99 per cent.

Modified constructions are available for high vacuum installations, such as pneumatic conveying of grain or coal, and also industrial vacuum cleaners for boiler houses, flue ash removal, and a variety of other purposes.

HOWDEN CENTICELL DUST COLLECTOR.

(James Howden and Co., Ltd., 195 Scotland Street, Glasgow, C.5.)

Application.—The Howden Centicell Collector is a centrifugal type dust collector for high efficiency extraction of fine dusts which are air or gas-borne. The design is varied according to the type of dust to be extracted, and to the conditions of service. For example, applied to steam raising plant, small cells are used for the extraction of dust from the flue gases of pulverised coal-fired boilers, while larger cells are used in the case of stoker fired boilers. Performance and size of plant can be varied also, depending on the design of inlet nozzle ring. The collectors are made with the cells either in the vertical or in the inclined position, and overall dimensions can be varied to suit most layouts.

Description.—The Howden Centicell Collector, a sectional view of which is shown in fig. 1, consists of a large number of small high efficiency dust separating cells. All the cells in one collector are similar, and each is composed of three units: (*a*) the cell body; (*b*) the inlet nozzle ring; (*c*) the clean gas or outlet tube. The dust-laden gas enters the inlet nozzle ring of each cell, and in passing through the nozzle ring it is given a spiral whirl which causes the dust particles to move radially outwards to the inside wall of the cell body. The separated dust discharges from the body through the bottom of the cell, and the clean gas moves into the outlet tube and flows away. The gas inlet chamber of the collector is common to all the nozzle rings, and the gas outlet chamber is common to all the outlet tubes.

The dust outlets from the individual cells discharge into common dust hoppers. These hoppers are divided up to form separate compartments which are sealed off from one another in order to reduce gas flow in the hopper between adjacent cells. This inter-cell flow tends to cause entrainment of the very fine dust particles already separated, and is accordingly detrimental to high efficiency operation.

Inter-cell flow is further counteracted by the pressure equalising system which creates a slight depression in the hopper compartments, this slight depression being sufficient to overcome gas flow from one cell to another. The gas flow through the pressure equalising system is about 4 per cent. of the main gas flow. This system comprises a fan with a small dust collector situated before it, and ducting connecting the small collector to the various compartments in the main hopper. The small dust collector is of similar design to the main collector and has its own dust hopper, the discharge point of which is brought close to the main dust discharge point. The clean gas from the pressure equalising system is led back into the outlet duct from the main collector.

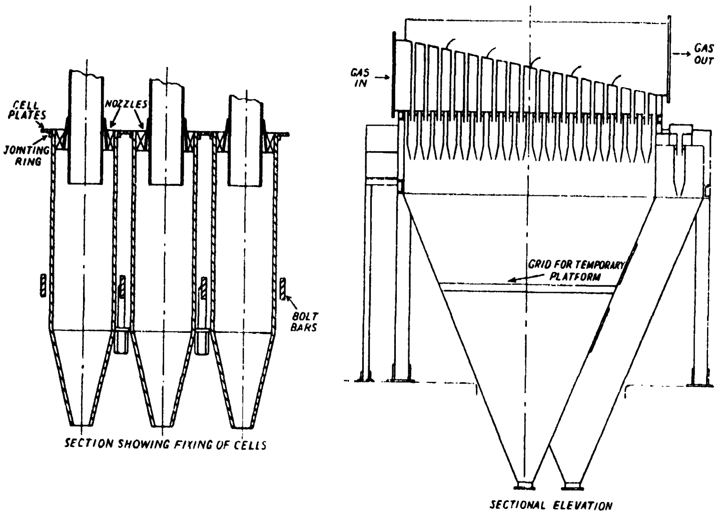


FIG. 1.

Interference between the gas whirls of individual cells, where these whirls still persist unprotected in the hopper compartments, is reduced to a minimum by a system of confluent whirls, thus ensuring high efficiency operation. With this system the gas whirls in adjacent cells are arranged in opposite directions of rotation so that, where the whirls persist unprotected, the gas motion in each whirl is in the same direction at adjacent points.

Performance.—The performance varies according to the size of the dust particles and the density of the dust presented to the collector. For example, when operating on flue dust from pulverised fuel-fired boilers efficiencies in excess of 90 per cent. are obtained, and on stoker flue dust efficiency lies between 95 per cent. and 98 per cent. Typical gradings for such dusts are as follows :—

Pulverised Fuel		Stoker	
Grade, microns.	Per cent. in Grade.	Grade, microns.	Per cent. in Grade.
Above 40	26	Above 421	22
40–30	14	421–296	12

Movement of Air by Fans.

The 'Wing' Fan.

(F. W. Potter & Soar, Ltd., Phipp St., Great Eastern Street, London, E.C. 2.)

The shape, curvature and angle of the blades have been carefully determined to give the highest possible efficiency. Although it has been found that an angle of 27½° to 30° is the best for combined output and efficiency, the mounting at the hubs allows for the adjustment of the blades to any required angle in order to fulfil special duties.

The Wing fan is made in all sizes and can be arranged for belt drive or direct coupling to motor.

When considering the application of propeller fans it is important to specify the direction of the air current in relation to the direction of running. The illustrations, termed Set A, B, C and D, show clearly the four cases to be considered.

Economy of Power.—Where conditions permit of the choice between a propeller type and a centrifugal type of fan, the following rules are useful :—

(*a*) For open ventilation use propeller fans.

(*b*) Make main air duct same diameter as fan, or larger, avoiding acute or sharp angle bends

(*c*) When small ducts and sharp bends are unavoidable use centrifugal fans.

(*d*) Use large fans at as low a speed as will overcome whatever resistance is in the way of free passage of air.

EXAMPLE.—A 10 ft. Wing fan at 90 revs. per min. delivers 71,000 cu. ft. of air per min., absorbing 1·2 h.p.

A 5 ft. Wing fan at 720 revs. per min. delivers 71,000 cu. ft. of air per min., absorbing 19·2 h.p. Volume for volume, therefore, the smaller fan uses 16 times the power absorbed by the larger fan.

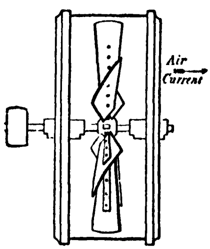
(*e*) Use two fans of the same diameter at low speed instead of one at double the speed.

EXAMPLE.—A 48 in. Wing fan at 600 revs. per min. delivers 30,200 cu. ft. of air per min., absorbing 3·6 h.p.

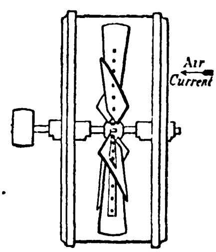
Two 48in. Wing fans at 300 revs. per min. deliver 30,200 cu. ft. of air per min., absorbing ·9 h.p. together.

Volume for volume, therefore, one fan uses four times the power absorbed by two fans.

SET A.

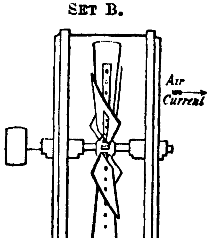


SET C.

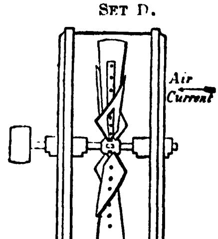


Viewing these fans from the pulley side, they both revolve in the same direction as the hands of a clock move, but the air currents are in opposite directions, as indicated by arrows.

SET B.



SET D.



Viewing these fans from the pulley side, they both revolve in a direction contrary to the motion of the hands of a clock, but the air currents are in opposite directions, as indicated by arrows.

SECTION XXXV

Refrigerating Machinery.

WATER COOLERS.

(Heenan and Froude, Limited, Worcester, England.)

The P type cooler manufactured by this firm and described separately on p. 1273, is particularly useful for employment with refrigerating machinery on account of its capacity for providing very cool water even in hot weather. Owing to its operating on the principle of evaporation, its capacity is controlled much more by the prevailing atmospheric wet bulb temperature than the dry bulb temperature, and consequently by suitably proportioning it to its duty, the water can be cooled down to a temperature closely approaching the wet bulb temperature.

Thus in hot weather, in both temperate and tropical climates, cooled water can be provided considerably below the dry bulb temperature of the surrounding atmosphere ; and as the efficiency and power absorption of refrigerating machines depend to some considerable extent upon their condenser temperatures, this is a most useful feature of the cooler. The apparatus is constructed entirely of metal and is self-contained, and the space taken up is very small in relation to its duty.

The refrigerating plant is rendered almost independent of town's water, and the cooler effects a large saving in water costs.

SECTION XXXVI

Compressors.

High Pressure Compressors.

(Peter Brotherhood, Ltd., Peterborough.)

Over sixty years ago the first Brotherhood high pressure compressors were made for supplying the air for the propulsion of the newly invented Whitehead torpedo, the pressure being 750 lb. per sq. in. This was the start of the development of the extensive range of high pressure compressors which has continued through the intervening years, so that there are, it is claimed, practically no conditions of pressure and capacity for which there is not a Brotherhood compressor.

Standard types cover all pressure up to 1,500 atmospheres and capacities up to the equivalent of 4,000 B.H.P. In one chemical works alone there are installed twelve high pressure compressors working on a system requiring a pressure of 3,500 lb. per sq. in. and driven through gearing by Brotherhood steam turbines developing between 1,500 and 3,500 B.H.P.

With the exception of the special type of compressors for oxygen, all machines are fitted with a special type of packing for the pistons which is claimed to ensure absolute tightness over long periods of continuous running.

A few typical machines are illustrated. Fig. 1 shows a two-stage double acting compressor specially designed for auxiliary service in motor ships, the pressure being between 350 and 450 lb. per sq. in. Fig. 2 shows a three-stage single crank compressor of capacity 400 cub. ft. of free air per minute at 1,000 lb. per sq. in. Compressors of this type are largely used for compression and liquefaction of CO_2, coal gas storage, auxiliary service in motor ships with air blast injection, and many other purposes. Two crank three-stage air compressors of more recent design for delivery pressures up to 600 lb. per sq. in. are available for supplying high pressure air for starting Diesel engines.

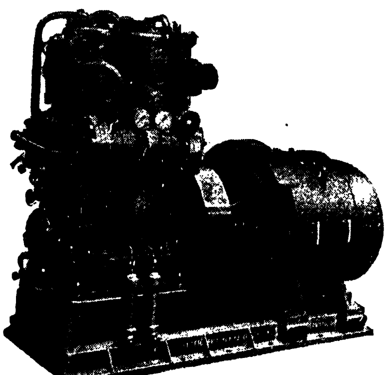

Fig. 1.
Two-stage Double Acting Compressor.

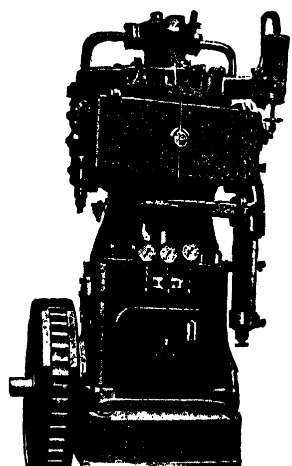

Fig. 2.
Three-stage Single Crank Compressor.

In fig. 3 is illustrated a five-stage three-crank gas compressor having an output of 400 cub. ft. of free air per minute at 5,000 lb. per sq. in. The largest high pressure compressors made in Great Britain are of generally similar arrangement.

Fig. 4 shows a four-stage air compressor for torpedo service in a submarine, the working pressure being 3,500 lb. per sq. in.

The Brotherhood compressors are also made for low pressures in one or two stages for all capacities up to 6,000 cub. ft. of free air per minute.

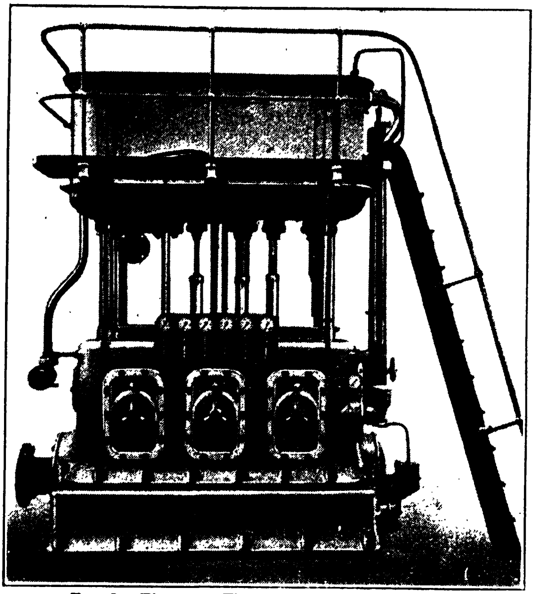

FIG. 3.—Five-stage Three-crank Gas Compressor.

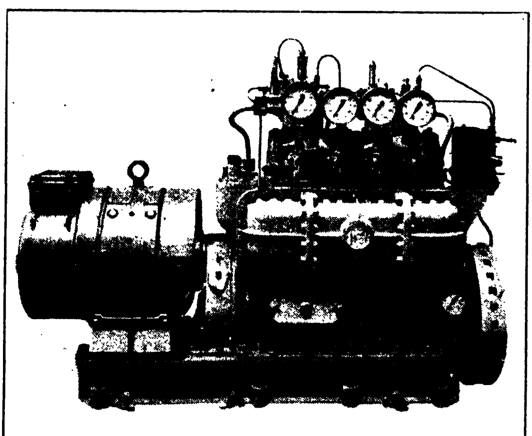

FIG. 4.—Four-stage Air Compressor.

High-Pressure Air Compressors.

(*G. & J. Weir, Ltd., Cathcart, Glasgow.*)

Fig. 1 shows a typical Weir four-stage, twin-crank, motor-driven air compressor for a delivery pressure of 4,500 lb. per sq. in. In this machine the first and second stages are formed by differential type pistons in two cylinders. The first stage of compression takes place in the tops of both cylinders, the air then passing through the first-stage intercooler and back to the second-stage which is formed in the annular space in both cylinders below the pistons. The third stage to which the air passes after leaving the second-stage intercooler is at the top of one of the differential piston rods and the fourth stage at the top of the other. There is of course an intercooler between these two stages. From the fourth stage the air passes to the pressure main

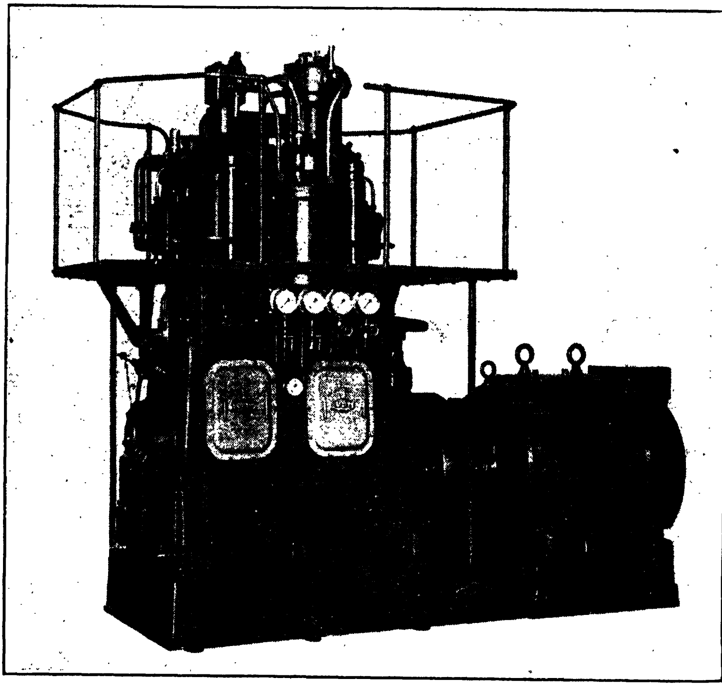

FIG. 1.—Weir four-stage, two-crank, motor-driven Air Compressor. 4,500 lb. per sq. in.

through the after-cooler. Oil and moisture separators are fitted to each intercooler and the after-cooler.

The pistons are of high-grade cast iron fitted with cast-iron rings of the Ramsbottom type With the perfected lubricating and cooling arrangements in the Weir compressor, the wear on these cast-iron rings over long periods of running is practically negligible, the tool marks being visible after years of running.

The air valves are of special design and the lift is exceedingly small, preventing undue shock and noise and obtaining a high degree of efficiency. The assembled valve units are arranged round the cylinder heads in such a manner as to reduce the cylinder clearance to a minimum, and give a resultant high volumetric efficiency.

All the running gear is forced lubricated by means of an oscillating type of oil pump. Cylinder lubrication is effected by a mechanical sight feed lubricator, feeding minute quantities of oil at

the correct points on the cylinder walls, and maintaining the thin even oil film so necessary with comparatively high-temperature conditions.

The foregoing description applies to compressors built for high pressure land service, but is also typical of three-stage compressors for pressures up to 1,000 lb. per sq. in., largely supplied for motor ship auxiliary duties, viz. starting, Diesel engine air-blast injection, manœuvring, etc. Other types include two-stage compressors for 450 lb. per sq. in. pressure, emergency tank-cooled compressors, and general service machines for all duties.

Fig. 2 illustrates a standard Weir four-stage, four-crank oxygen compressor for a delivery pressure of 4,000 lb. per sq. in. The first and second stages are double-acting, and the third and fourth stages single-acting, each crank carrying one stage only.

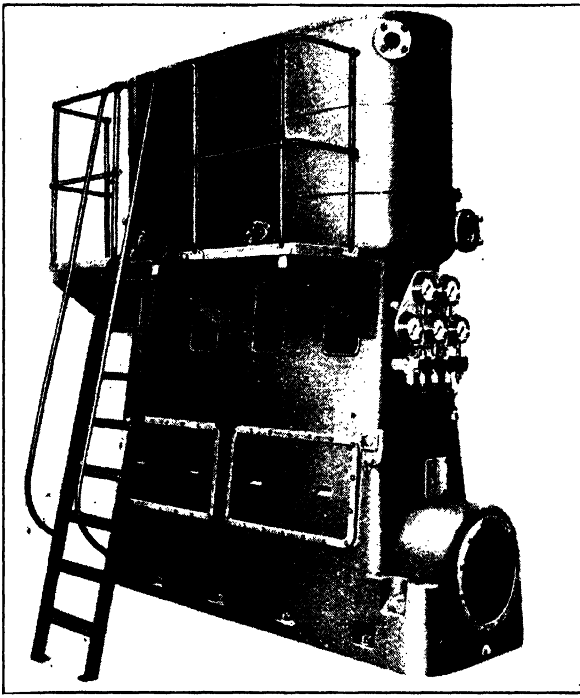

FIG. 2.—Weir four-stage Oxygen Compressor. 4,000 lb. per sq. in.

The whole of the cylinders and cooling coils are immersed in an open tank with an ample supply of cooling water to dissipate the heat of compression.

In compressing oxygen, oil must not be used for cylinder lubrication, as oil and oxygen form a highly explosive mixture. The cylinders therefore are lubricated with distilled water, which necessitates the use of corrosion-resisting materials and specially designed piston rings and liners to counteract undue wear caused by the poor lubricating properties of distilled water.

The piston rod glands are water sealed to prevent any leakage of oxygen to the atmosphere.

The running gear is totally enclosed and forced lubricated throughout by means of an oscillating type lubricating oil pump.

Compressors dealing with oxygen and other industrial gases for delivery pressure ranging to 6,000 lb. per sq. in. are constructed, and may be arranged for drive either by electric motor, independent steam engine, tandem steam engine, or oil engine.

Water Coolers.

(Heenan & Froude, Limited, Worcester, England.)

The P type cooler manufactured by this firm and described separately on p. 1273, is particularly useful for employment with air compressors on account of its capacity for providing very cool water even in hot weather. Owing to its operating on the principle of evaporation, its capacity is controlled much more by the prevailing atmospheric wet bulb temperature than the dry bulb temperature, and consequently by suitably proportioning it to its duty, the water can be cooled down to a temperature closely approaching the wet bulb temperature.

Thus in hot weather, in both temperate and tropical climates, cooled water can be provided considerably below the dry bulb temperature of the surrounding atmosphere; and as the efficiency and power absorption of air compressors depend to some considerable extent upon the temperature of the circulating water, this is a most useful feature of the cooler. The apparatus is constructed entirely of metal and is self-contained, and the space taken up is very small in relation to its duty.

The cooler can deal with the water of inter-coolers and after-coolers if required, thus reducing the final air temperature and minimising condensation in the exhaust from compressed-air tools, etc.

The air compressor is rendered almost independent of town's water, and the cooler effects a large saving in water costs.

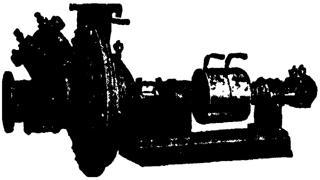
SECTION XXXVII

Sanitary Engineering.

THE 'STEREOPHAGUS' PUMP.

(The Pulsometer Engineering Co., Ltd., Nine Elms Works, Reading.)

The 'Stereophagus' pump is designed to deal with unscreened sewage, and, as it cuts up the solid matter in suspension to small pieces, the sewage as it leaves the pump is easily dealt with during subsequent treatment. The pump is simple and substantial in construction, and is low in installation cost as well as in maintenance.



It is equally suitable for dealing with trade effluents containing obstructive matter of any sort. The problem of pumping fluids containing flocculent or fibrous matter has always been a difficult one, and though a large variety of pumps has been tried, trouble from choking has always remained a pronounced feature. In reciprocating pumps, the choking of the valves is a great source of trouble, and in the case of centrifugal pumps, the clinging and accumulating of flocculent matter to the spindle and impeller necessitates frequent stoppages for cleaning. The 'Stereophagus' pump overcomes all these troubles.

SECTION XXXIX

PART I

Mining.

COAL FACE MACHINERY.

(Mavor & Coulson Limited, Glasgow and Sheffield.)

Longwall Coalcutters.—The modern chain coalcutter has become so powerful and adaptable that it has superseded all other types. The Samson coalcutter, for example, can cut longwall faces up to 8 ft. deep, and cuts at speeds up to 5 ft. a minute. Areas of 3,000 to 4,000 sq. ft. are regularly cut in the shift, and more on occasion.

The introduction by M. & C. of the spiral gummer has further improved longwall coalcutter performance. The gummer consists of a short worm conveyor, which takes away the holings as brought out by the cutter chain, and places them either at the side of the machine or behind it, according to the type of gummer. The advantages are: (1) Increased safety. The gummer completely encloses the cutter chain on the driving sprocket, both from the goaf side and from the end of the machine. There is no longer any need for a man to work close behind the machine, an especially important point under bad roof. (2) Greatly reduced fine dust. What dust is made is kept on the floor, buried under the larger holings, which come to the top. (3) The arduous work of shovelling away the holings as they are brought out is avoided. The gummer takes away at least 80 per cent. of the holings—far more than could be done by hand. (4) Power is saved, because the holings are no longer churned by the picks. (5) Picks keep sharp longer and cut further because they are not blunted by churning the holings. The time taken in changing picks is also reduced. (6) Other moving parts are given longer life, and the cost of replacements is correspondingly reduced. (7) Samson coalcutters with gummer travel freer and faster. (8) Better coal preparation. Any holings left in the cut are near the front, and the back, which is so hard to clean by hand, is left clear. The coal therefore shoots better, and explosives may also be saved.

Arcwall Coalcutters.—M. & C. arcwall and arcwall-and-sheering coalcutters commonly carry a jib 9 ft. long, making an arc cut up to 9 ft. deep at the end of a 'room' 21 ft. wide. Under favourable circumstances, the jib can be 11 ft. long, cutting 25 ft. wide. The machine travels from room to room, either on rail wheels or on crawlers, and may regularly cut more than 20 rooms in one shift. The machines usually have a 60 h.p. motor, and weigh from under 4 tons to over 7 tons.

Face Belt Conveyors.—A very widely used type of face conveyor is the flat belt running between side plates. The side plates make filling easier, reduce spillage, and protect the belt. When running at 150 ft. per minute with average loading, the belt has the following capacity:

Width of Belt.	Tons of Coal per Hour.
20 ins.	75
24 ins.	90
26 ins.	100

The structure of M. & C. face belts is formed of inverted troughs, which keep all dirt from reaching the return belt, no matter how coal is shovelled against the conveyor or how dirt rolls against it out of the goaf. The inverted troughs allow the belt to run under conditions where an unprotected trough would suffer severely.

Roadway Conveyors.—A pre-eminent conveyor for mining roadways is the troughed belt, introduced for large-scale underground conveying by M. & C. The capacity of M. & C. troughed belts handling run-of-mine coal is as follows:

Width of Belt.	160 ft./min.	260 ft./min.	340 ft./min.
24 ins.	80	130	170
26 ins.	100	165	210
30 ins.	140	230	300
36 ins.	200	330	430
42 ins.	—	490	640

As with the flat belts, these troughed belts are kept safe from damage by inverted troughing which completely covers them. The method by which the rollers are mounted on ball bearings reduces the friction to the lowest possible amount, and allows a smaller motor to be used or the

conveyor to extend further. When conveying up more than 1 in 16, the belt is kept from running back by a holdback. When conveying down steeper than 1 in 16, the belt is brought to rest by a brake, which is applied automatically when the electric or air supply is cut off the motor. The loading of large outputs into tubs is facilitated by a shaking chute, and the tubs can be handled beneath the discharge point by a tub-pusher. Extending the conveyor daily to keep up with the advancing face is simplified by the M. & C. loop take-up, which also gives an easy way of tensioning the belt.

M. & C. Loaders.—M. & C. Loaders are mobile machines for loading coal or other loose material. After the coal has been undercut and blown down, the loader advances on its crawlers and thrusts its gathering head into the heap. While it does so, two gathering arms, acting alternately, sweep and pull the coal on to the chain conveyor, which carries the coal to the end of a flexible jib and delivers it into tubs, shuttle cars, or a conveyor.

Hydraulic movements raise the gathering head off the floor for travelling, and slew or raise the jib, in order to deliver the coal just where required. These machines load large quantities of loose coal in mechanised room and pillar mining, and also have enabled stone-drifts to be driven at over 40 yards a week.

SECTION XLII

Paint and Painting Equipment.

GRAPHITE PAINT.

(*Graphite Products, Ltd.*, 52 *Battersea Church Road, S.W.* 11.)

The best and longest records of satisfactory protection against corrosion are said to be held by paints made with tough crystalline foliated graphite containing silica within its structure.

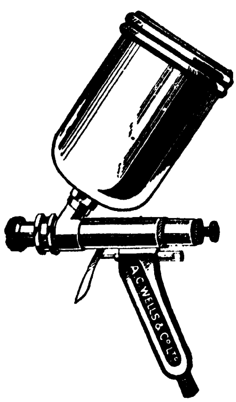
An example of this is the 'Foliac' Silica-Graphite Paint, manufactured by Graphite Products, Ltd., Battersea, which is British manufactured throughout, and has been specified for a large number of steel structures, including aerodrome buildings, oil fuel tanks, gas holders, docks, bridges, station roofs, railway wagons, etc.

The relative covering power of foliated silica graphite paint is very high, and owing to the light weight lubricating properties of the pigment the speed of application to the surface is very much more rapid than with other linseed oil paints. Owing to the large adhesion surface between the vehicle and the foliated graphite a very flexible tough paint is obtained which stands wearing action due to dust, for example, much better than paints which become brittle on drying. The resistance of the pigment to the action of the atmosphere found in industrial districts is due of course, to the fact that it is chemically inert.

SPRAY PAINTING EQUIPMENT.

(*A. C. Wells & Co., Ltd., Mount Street, P.O. Box* 5, *Hyde, Cheshire.*)

Spray Guns.—Of recent years the application of paints, varnishes, stains, fillers, french polishes, distempers, etc., by the spray method has become more general. The Spray Guns are fitted with a range of nozzles for different purposes, and consume 4/8 cub. ft. of compressed air per minute at pressures of 40/60 lb. per sq. inch. The Standard Gun is fitted with an adjustable nozzle whereby the deflector holes in the nozzle can be set to produce a round or flat spray. Generally the flat spray is about 6 ins. wide, but if the gun is being used with a Pressure Solution Container, this width can be increased to approximately 10 ins.



Solution Containers.—The solution to be sprayed is supplied to the gun either by a small container attached above the gun, when the solution falls by gravity, or below the gun where the solution is taken up by suction. It is not practicable, owing to the weight, to have these containers more than one pint or in exceptional cases, one quart capacity. In many instances, therefore, it is usual to supply the solution to the guns from gravity or pressure containers of suitable capacities. The latter type gives a wider spray, as the solution reaches the nozzle under pressure.

A full range of pressure containers is made in capacities up to 50 gallons.

Air Compressors.—The air for the gun is supplied from standard air compressor units which can be arranged either in portable or stationary form, to be driven by electric motor, petrol engine or other form of power.

Air Filters.—It is necessary to have clean air free from dust, oil or water for the spray gun, to ensure satisfactory action of the spray gun and a clean, unblemished finish of the work. In each equipment, therefore, an air filter is necessary. This is usually supplied with an air reducing valve, which enables pressure to be set to a suitable limit for the solution being sprayed. The air filter itself is in the form of a welded steel container with a perforated tube fitted with absorbent filtering material. This filtering material can easily be replaced or dried.

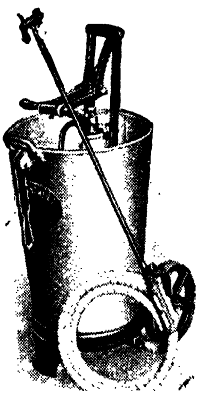
Air Receivers.—These welded steel vessels are placed in the air line between the compressor and air filter. The effect is to balance the impulses from the compressor and allow the water of condensation to settle out.

LIME SPRAYERS.

(A. C. Wells & Co., Ltd., Mount Street, P.O. Box 5, Hyde, Cheshire.)

These machines take the place of the old method of limewashing with a brush. Lime, whiting or cold water paints can be applied at a speed of from 10 to 20 sq. yds. per minute in a manner superior to brush work. One coat with this machine on rough or dirty surfaces is claimed to equal two applied with brushes. The material is applied in the form of a spray, and is driven into corners and difficult places where a brush would not reach.

Limewashing machines will spray all water preparations, but will not use oil-paints or varnishes. For the latter, compressed air is necessary to break the liquid up into a spray, necessitating special plant coupled to the user's own air main or suitable compressor.



Lime washing machines can be arranged to spray solignum, creosote and other wood preservatives, also insecticides of every description. In this connection the No. 6 machine is specially recommended.

These machines are designed to withstand rough usage. They are made of durable materials, which, although adding to the initial cost, effect a great economy in their life and upkeep.

The spraying nozzle is the nerve centre of a lime washing machine, and its construction is, therefore, a most important feature. The nozzle can be regulated to any degree of fineness by means of the spray regulator, while the patent filter prevents clogging. The whole can be cleaned easily, and replaced quickly. An additional and essential feature is the ability to swivel the nozzle to any angle, thus greatly assisting the operator and enabling a right-angled spray to be brought to bear on any surface.

The pump is simple and easily removable, while the bell-handle and trigger valve provide a comfortable grip and an immediate control over the spray by the mere pressure of the hand. Attention is called to the air chamber, which is constructed of sufficient size to enable an even spray to be maintained without continual pumping.

SECTION XLVII

(Unclassified.)

Diving Apparatus, etc.

DIVING APPARATUS; BREATHING AND RESUSCITATING APPARATUS, ETC.

(Siebe, Gorman & Co., Ltd., Davis Road, Tolworth, Surrey.)

The firm of Siebe, Gorman & Co., Ltd., was established in London by Augustus Siebe (1788–1872) in the year 1819. Siebe was a mechanical genius whose versatility covered the invention not only of diving apparatus, on which his fame chiefly rests, but also such widely different productions as printing machines, clock-work mechanisms, weighing machines (including the first height-and-weight machine, of which he supplied a number to the Government during the recruitment of troops for the Crimean war; one of these machines is still in the firm's possession), air pressure and water gauges, valves, air and water pumps, electrical apparatus, etc. He made, in 1850, the first practicable steam-driven ice-making machine (James Harrison's patents) produced

FIG. 1.

FIG. 2.

in England, and exhibited it at the great exhibition held in London in 1851. In 1823 he received the Silver Vulcan medal of the Royal Society of Arts for one of his inventions. He was an associate of the Institution of Civil Engineers.

Siebe made his first 'open' diving dress in 1819—*i.e.* a helmet attached to a jacket which extended to just below the waist, and functioned like a diving bell. In 1837 he invented the closed diving dress and helmet on the principle which is still in universal use. No matter what the shape of the helmet, type of valves, and method of securing to the rubber dress, the principle remains Siebe's throughout the world.

Siebe died in 1872, and was succeeded by his son, Henry Siebe (1830–1885) and son-in-law, W. A. Gorman (1834–1904), who had been Siebe's assistants for many years. The present head of the company is Sir Robert H. Davis (who entered the firm in January 1882 and served under

Henry Siebe and W. A. Gorman). With him as co-directors are his sons, R. W. Gorman Davis and W. Eric Davis; while his son, R. J. (Peter) Davis, is also in a managerial position.

In the firm's possession are the originals of a number of orders received by A. Siebe over a hundred years ago from the Admiralty for diving appliances, etc., for various naval establishments at home and abroad, and for work at the wreck of the *Royal George*, sunk at Spithead in 1782.

The firm is probably the oldest maker of air pumps (pressure and vacuum) in the world. It is certainly the oldest maker of diving and other submarine appliances, of gas masks and self-contained breathing apparatus for work in poisonous atmospheres, and of oxygen breathing apparatus for airmen flying at great altitudes

It had already for many years before 1879 been producing smoke helmets and breathing apparatus of the fresh air type, but in that year the firm turned its attention to the design (in collaboration with Henry A. Fleuss) and manufacture of breathing apparatus on the self-contained regenerative system, using compressed oxygen with CO_2 absorbents. In the same year it produced the first really practicable apparatus of the kind, and this was actually used at the

FIG. 3.

FIG. 4.

Killingworth Colliery, after a disastrous explosion there, in 1880; also at the Seaham Colliery. The same principle was also adapted to Siebe, Gorman & Co.'s diving dress with good results. It should be added that both apparatus on this principle, *i.e.* for work in poisonous atmospheres and under water, are the prototypes of all apparatus of the kind used throughout the world.

The Siebe-Gorman diving apparatus with air delivered to the diver by means of manually-worked pumps, or by air compressors—electrically, steam or oil engine driven—are so well known that we are not describing or illustrating it here. The following may, however, interest the reader:

Fig. 1 illustrates a self-contained diving apparatus consisting of the usual Siebe, Gorman & Co., diving dress and helmet with corselet; a steel cylinder charged with a mixture of pure oxygen and atmospheric air at a pressure of 1,800 lb. per sq. in.; a reducing valve and injector, delivering automatically the requisite quantity of oxygen, and circulating the air in the helmet and dress through the CO_2 absorbent.

The 'Proto' self-contained breathing apparatus (fig. 2) is used largely for rescue and recovery work in mines, and by fire brigades, gas works, chemical works, etc. It consists of a combined flexible breathing and CO_2 absorbent chamber carried in front of the wearer, a steel cylinder, charged with pure oxygen at 1,800 lb. per sq. in., carried on the back, with a reducing valve passing oxygen automatically into the breathing bag at a constant rate at all stages of pressure in the cylinder; a mouthpiece attached to flexible corrugated tubes fitted with inspiratory and expiratory valves connected to the breathing-absorbent chamber. The latter is divided by a

partition, the exhaled air passing through the expiratory valve, down one side of the partition, through the absorbent, and returning, purified, on the other side of the partition, through the inspiratory valve. Adjacent the latter valve is delivered the stream of fresh oxygen from the reducing valve. An oxygen by-pass is fitted in case of emergency, and a pressure gauge, attached

FIG. 5.

to a high pressure flexible tube, registers the amount of oxygen in the cylinder and the duration of its supply. The wearer's nose is clipped, breathing being done by the mouth only, so that, doing hard work, he is quite safe in the most poisonous or oxygenless atmosphere for at least two hours at a time.

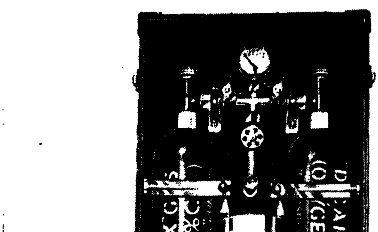


FIG. 6.

The 'Salvus' self-contained breathing apparatus, illustrated in fig. 3, is on the same principle as the 'Proto,' but in this case the apparatus is carried wholly in front of the wearer, and is suitable for only forty minutes' work in poisonous atmosphere. The CO_2 absorbent cartridge is separate from the breathing chamber.

Gas masks for use in all kinds of poisonous air encountered in industry, including carbon monoxide, as well as the various war gases are made (fig. 4).

Other forms of breathing apparatus are the 'Spirelmo' smoke helmet and 'Puretha' mask supplied with fresh air by means of bellows, blowers or pumps, and the 'Antipoys,' with which the wearer draws his supply of air by his own lung effort through a tube, the free end of which is kept in open fresh air; compressed air apparatus consisting of a cylinder or cylinders or atmospheric air with a lung governed breathing device, mask, etc.

Figs. 5 and 6 show the 'Novox' resuscitating apparatus for reviving the apparently drowned and persons suffering from shock. The apparatus consists of a cylinder of pure oxygen with 7 per cent. of carbon dioxide, and a lung-governed breathing device, in a flexible chamber, which gives the patient automatically more or less of the gaseous mixture, according to his needs. The addition of the 7 per cent. CO_2 stimulates the respiratory centre, causes the wearer to take in more oxygen and so hastens expulsion of the poison from the system.

Another important apparatus produced by the firm is the Davis submarine escape apparatus, the invention of Sir Robert Davis.

During the 1939–45 War much of the firm's effort was devoted to the design and production of special equipment for underwater warfare which included apparatus for the crews of 'Human Torpedos,' Midget Submarines and submersible canoes, mine recovery apparatus, etc.

The Admiralty Experimental Diving Unit, formed in the early part of the war, was located at the firm's works where the full resources of its Experimental and Research Department were placed at its disposal.

Linatex Rubber.

(*Wilkinson Rubber Linatex Ltd., Frimley Road, Camberley, Surrey.*)

Linatex is a special form of proprietary rubber manufactured direct from fresh rubber latex It has great resilience and a high resistance to abrasion and perishing. It can be built up by cold cementing processes to conform to any required shape.

Special cements are available for bonding Linatex to wood, metal, or concrete, and additional mechanical anchorage can be achieved by metal straps.

The following notes will give some indication of the many applications of this material :—

Air Conditioning Equipment.—For flexible trunkings, fan and fan-blade-coverings, Linatex 95 per cent. pure natural rubber can be employed. It is also suitable for the lining of ductings in ventilation and extraction plants.

Aircraft Accessories.—Flexatex hose is still used for aircraft petrol and nitrogen systems. A wide range of sealing sections for window frames and pressurised cabins can be supplied in either Linatex or Novatex, depending on location and working conditions.

Anti-Vibration Mountings.—Linatex 95 per cent. pure natural rubber has been found eminently suitable for damping vibration. The makers undertake to tackle each problem individually—from a steam hammer to a small camera mounting.

Centrifugal Pumps.—Pumps particularly suited for handling ash, sand, gravel and corrosive chemicals are built in Linatex from 1-in. to 9-in. bore. It is claimed that an impeller of practically solid Linatex rubber will outlast steel in such applications.

Coal and Ash Handling Plant.—The special anti-abrasion properties of Linatex, the makers state, can be employed in this sphere with good effect. Chute and hopper linings will outlast steel, and the Linatex pump cannot be used to better advantage than in the handling of ash sludge.

Cocks, Valves and Pipe Fittings.—Linatex cocks and valves are now being produced for the handling of slurries in sand, gravel, slime and corrosive chemicals. In their design attention has been paid to full-bore flow, positive seating and the need to withstand heavy abrasion.

Gaskets and Jointing Materials.—A wide range of gaskets made from Linatex 95 per cent. pure natural rubber is now in use. Where Linatex is unsuitable, gaskets in Novatex are supplied. This is a rubberlike material which effectively resists the action of oils and petrols.

Hose Pipes and fittings.—Hose lines of Flexatex continue to have a wide field of use in aircraft. This hose is made from a plastic material chosen for its resistance to oils, fuels and gases. It is also used in the handling of chemicals.

Lining (Rubber).—Linatex lining of gravel plants and chutes has proved of great benefit on the score of resistance to abrasion. It is also widely used for lining acid tanks, pipes, and ductings for fume-extraction plant.

Mills (Ball and Pebble).—Designed to use Linatex anti-abrasion rubber in compression, which is its best condition for resistance of abrasion, Linatex ball mills not only show better grinding times, but preclude the possibility of rubber linings working loose. The wear is negligible over a period of years.

Plastic Materials.—Novatex is a proprietary rubberlike material, suitable for extruded sections, oil and petrol-proof gaskets, and in general can be used where rubber is precluded.

Rubber.—The anti-abrasion qualities and resilience of Linatex 95 per cent. pure natural rubber have now established it firmly as a basic engineering material during twenty-five years of universal application in mining, chemical and engineering spheres.

Seals and Sealing Sections.—Any shape or size of seal can be fabricated in Linatex, and where excessive oil is present alternative materials can be used.

Pneumatic Despatch Tubes.

(*Lamson Engineering Co., Ltd.*, 6, 7 *&* 8 *Hythe Road, Willesden, London, N.W.* 10.)

Pneumatic Tubes are used by stores for handling cash and credit transactions, by industria concerns for conveying papers, samples, small articles, etc., between departments and buildings. They are also used in many Government departments, warships, aerodromes, etc.

There are two methods of effecting transmission by pneumatic tubes—the 'single' and 'double' tube systems. The former consists of a single tube and can be used for transmission in either direction by reversing the flow of air. To-day, this system is usually confined to long lines operated by pressure. The 'double' tube comprises two tubes, by which a continuous supply of air passes down one tube and returns by the other, to the exhauster. This system is usually worked on suction; carriers are thus allowed to travel in both outgoing and incoming tubes at the same time. Even the simplest communications, such as those connecting two points only, are carried out by double tubes with a small motor-driven exhauster applied to one end of the tube. The cost of such a system is low, and when equipped with push-button start and automatic stop, the amount of electric current used for intermittent operation is negligible. 'Double' tube systems may be either of the 'independent line' type when continuous service at will in either direction is provided, or they may be constructed on the 'shifting' plan, in which case the service is, to a certain extent, restricted. In either instance suction only is employed. 'Shifting' lines have one tube—common to two or more stations—on the incoming line to a central desk, but an independent outgoing tube to each out-station.

Any number of tubes may be connected to a central station, and these, in turn, through a main vacuum or pressure pipe, are connected to the exhauster, which usually operates continuously. Where there is a large number of stations, only a proportion of which are in simultaneous use, means can be provided to reduce automatically the speed of the exhauster, or to reduce the load on the machine, to suit the number of tubes in use and so effect a considerable reduction in power cost.

The motive power for operating the pneumatic tube system can be a turbine or Roots type blower. The usual practice, nowadays, is to use the turbine. The size and type of machine depend upon the diameter and length of tube or tubes through which the carriers have to travel, and the requirements of service. There is practically no limit to the length for a pneumatic tube, but for abnormal lines it is necessary to use pressure.

Tubes of 2¼ in. diameter are generally used. 40 mm. tubes are common in hotels, restaurants, etc., for conveying service chits and checks. Other typical sizes for samples, small parts, books and files, large documents, newspaper 'fudge' and matrices are 3 in., 4 in. and 10 in. diameter tubes, 7 × 4 in., 13 × 5 in. and 14 × 9 in. oval tubes.

Where cash is being handled, the central desk is usually designed as follows :—

'*Belt Operated*' *Type.*—Carriers arrive at the desk and are conveyed on a moving belt to the cashier; the change is made and carriers are placed on another belt, which takes them to despatching centre, whence they are returned to sales stations in the store. The flexibility of this type of desk allows the system to be operated by only one, or more than seventy cashiers, according to the size of the store or fluctuations in business. Patent carrier-operated separators automatically transfer credit and account transactions to a credit office for authorisation.

'*Gravity*' *Type.*—This desk is designed for smaller installations up to thirty stations. The incoming tubes are arranged at one or both ends of the desk. Carriers are delivered from terminals into a chute, down which they travel to operator. Despatch terminals are located at the centre or end of desk to facilitate speedy return of carriers.

With both 'Belt' and 'Gravity' operated desks, carriers are handled by operators in consecutive order of their arrival.

A new type of system now being installed in this country is the Carrier Operated Switch System, whereby carriers travel through an endless tube and are automatically discharged at any point by means of an electrical impulse which is set up through previous adjustment by the operator of interconnected indicating rings on the carriers.

The principal advantages of this system are that all stations inter-communicate without the necessity for a central desk and therefore the usual double tube between central desk and outstations is not needed.

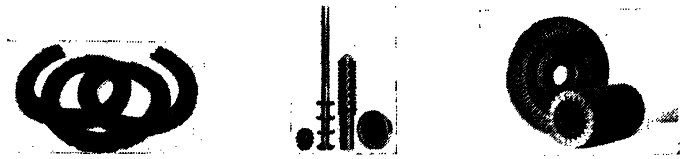
Brushware.

(*Kleen-E-Ze Brush Co. Ltd., Hanham, Bristol.*)

There was a time when, apart from catering to household and decorating needs, brushmakers met such demands as were made by industrial requirements from their limited stocks, either in

standard or slightly modified form. In other words, industry had to 'make do' with what was available. Now brushmaking is recognised as a specialised manufacturing industry.

Whilst there was a trend in the direction of creating brushes for specific industrial needs before hostilities, the war definitely gave impetus to this service and it is now possible to apply the expression 'industrial brushware of every description to customer's needs' or some such phrasing in actual truth!



Kleen-E-Ze Brushware.

Examples of specialised productions include:—

(a) *Component parts.*—'Brush-form' coils, 'Brush cloth' in many types, 'Multibrush' fibre units, brush guides, etc.
(b) *Processing 'tools.'*—Decarbonising brushes, wire wheels, polishing heads, scouring brushes, 'Kezas'—scalariform coiled units for cleaning unloaded supply tubes, internal tube burnishers, lacquer, paint and oil brushes, etc.
(c) *General production.*—Scruffing, burnishing, suds and tube brushes; polishing soap, bench, foundry, laboratory and maintenance brushware, etc.
(d) *Cleaning purposes.*—Platform and yard brooms, sweeper, dusting, polishing and hand brushes; scrubber, stencils, pipe, paint and varnish brushes, etc.
(e) *Personal use.*—Washroom brushware including hair, clothes and nail brushes, etc.

This firm's policy for the past twelve years has embodied a scheme of training technical representatives able to make first-hand investigation of specific requirements and to submit recommendations of brushware with full details of processing, etc. It has created over 9,000 types ranging from a small applicator with a ¼-in. head by ⅛-in. dia. to roller brushes (single-unit-type) 15 ft. long with a 6 ft. periphery. This has necessitated making scale drawings and models, often introducing mechanical operational arrangement, incorporating a variety of materials for laboratory tests to determine final needs and approval. Such a service to the customer has its appeal and means that the fullest possible experience is being given to solving his particular problem.

How many times has a mechanical device been in course of manufacture when it has been discovered that a small but essential unit does not function properly or has been designed on the drawing board and is technically wrong? Undoubtedly brushes come high in such a list of circumstances. Just now, for example, there is a spate of new designs, either in or just out of the prototype stage, requiring a brush component but it can be taken for granted that in only a small proportion of cases will the manufacturer have the advantage of preliminary discussion with a brush maker who is in the position to know all the snags of types, materials, lay-out, etc., and thus to learn the exact type around which the device can be built.

Brushing problems apply to the engineering world whether it be the aircraft, motor, shipbuilding, ordnance, locomotive or other classes. All have their separate and individual problems and would do well to take advantage of the services of any firm offering technical advice. A price-list will be a useful reference for ordinary needs, of course, but how can any firm give stock advice, literally or pictorially, that can be certain to fill a technical application?

Many cases can be cited when brushware designed for a special purpose has contributed towards the solution of problems widely varied in character yet closely allied in operation. One such was the result of an enquiry of an almost casual nature during practical experiments in high-altitude flying with liquid oxygen converters. It was suggested that a special component that was used as an oil-flow breaker might be modified to form a unit to fill a function that was not being obtained satisfactorily. Not only did the ultimate design meet the need, it reduced the vertical dimension of the apparatus by 50 per cent., a feature not even considered in the first instance!

To-day the brushmaking industry is expanding to meet the growing needs of engineers and manufacturers generally, who are finding new uses for brushware that can be made in so many forms to fulfil special purposes. This growth in the variety of brushware, has, of course, turned the trade from the simplest of processes to a complicated and precise manufacture embodying elaborate wood-working engineering and allied trades within its own. For example, a brush-head itself in the form of manufacture required, necessitates turning, spindling, routing, double-drilling mechanical dividing, mechanical knot picking, filling, trimming, capstan and centre-athe work, riveting and assembly.
